Recently genetic linkage and genome-wide association studies in individuals with increased levels of HbF or hereditary persistence of fetal hemoglobin (HPFH) syndromes have provided new and important insights in the control of fetal to adult globin switching.[420,421] Of interest, besides cis control of switching (deletions in β-globin cluster or mutations in the γ-globin gene promoters), trans control was revealed through direct and indirect interactions of γ-globin with molecules (controlled by loci unlinked to the β-globin cluster) exerting repressive fetal globin activity. These molecules were BCL11A, a transcription factor involved in juvenile leukemia, and HBS1L-Myb. The full-length BCL11A is expressed in adult but not fetal erythroid cells, and adult individuals with high hemoglobin F/BCL11A genotype have reduced expression of full-length BCL11A. Suppression of its expression reactivates HbF expression in adult erythroid cells in vitro,[422] and deletion of BCL11A interferes with fetal hemoglobin silencing during development and rescues the phenotype of a mouse model of sickle cell disease.[423] Myb-HBS1L is downregulated in individuals with elevated HbF levels and overexpression of Myb inhibits γ-globin in human erythroleukemia cells. The levels of Myb were found to be controlled by micro-RNA 15a and 16-1 in patients with human trisomy 13 and high HbF levels.[424] In addition to the above molecules with γ-globin repressive activity, recent data support a role of KLF1, the major erythroid transcriptional regulator, in globin gene switching. Valuable insights were obtained from families with haploinsufficiency of KLF1 (missense mutations affecting DNA binding) and increased fetal hemoglobin levels.[425,426] However, this was not always the case, and a compound heterozygosity was required in other families for high HbF expression.[427] It appears that KLF1 targets genes such as BCL11A, EPB4.9, and CD44, which are very sensitive to KLF1 activity, whereas effects on other genes like γ-globin, or BCAM (carrying the Lutheran blood group antigens) are variable. Collectively, it turned out that KLF1 has a critical role in globin gene switching both by directly activating β-globin and indirectly by suppressing γ-globin through its control of BCL11A. Overall, genetic data account for approximately 70% of the HPFH phenotypes observed in human populations, suggesting that new factors are yet to be identified. In this context, it is of interest that three β^0-thalassemia major patients who failed to engraft after stem cell transplantation became transfusion independent because they expressed sustained levels of increased HbF in autologous red cells post transplantation without evidence of any known HPFH genotypes.[428] From all of these studies, it has become apparent that switching is very complex, involving many players, cis and trans, with distinct and variable roles. The many models of globin switching proposed previously (i.e., the competitive model, the chromosome looping, the gene silencing) are not mutually exclusive and may complement each other.

In summary, throughout human development, waves of hematopoiesis are initiated sequentially in newly recruited sites. The first wave of erythropoiesis is seen in yolk sac between days 15 and 18 (7.5 days after conception in mice). In addition to erythroid cells, uncommitted progenitors and progenitors for nonerythroid cells are present in the yolk sac and are thought to be the source of cells colonizing the fetal liver.[195,429-431] However, in addition to yolk sac, foci of hematopoietic activity have been detected within the embryo around the developing aorta (in para-aortic–splanchnopleura [P-Sp] and aorto-gonad-mesonephros [AGM] area).[432-434] In fact, the P-Sp/AGM site in mice was shown to harbor progenitor cells before circulation begins and 1 day before these cells are found in the yolk sac. Long-term repopulating cells after their transplantation in adult recipients were detected only in the AGM area, leading to speculation that this intraembryonic site is the main or only source of fetal liver colonization,[434] in contrast to earlier experiments implicating the yolk sac in that role.[429-431] Establishment of blood flow and the concentration of nitric oxide appear to play an important role in determining the number of definitive hematopoietic stem cells generated in the AGM region.[435] Presence of mesodermally derived hematopoietic cells in two distinct anatomic sites, one intraembryonic and the other extraembryonic, has been seen in explant studies of *Xenopus* and after analysis of chick-quail chimeras.[436] More recent experiments with human cells have led to similar conclusions.[437] Although the presence of progenitors for definitive hematopoiesis in two independent sites (extraembryonic and within the embryo proper) is indisputable, the extent to which these two sites contribute to fetal liver colonization has been a matter of dispute. The conclusion that only the AGM area contributes to fetal liver colonization was based on transplantation experiments in adult recipients and has been challenged.[361] Transplantation experiments using newborn mice with active fetal liver hematopoiesis as recipients showed that adult long-term repopulating cells are detectable in the yolk sac at day 9 post conception and are 37-fold greater in number than repopulating cells present in the P-Sp/AGM area at the same time. Therefore failure of yolk sac cells (or AGM cells before day 10 post conception) to engraft adult recipients may be caused by either compromised homing or impaired survival and proliferation within the adult bone marrow environment (because of positive regulators or inhibition by negative regulators). In light of this information, the 30-year-old theory that yolk sac colonizes the fetal liver has been revived.[429] A question that remains unanswered is whether stem cell activity 9 days post conception in yolk sac and P-Sp/AGM is generated autonomously and independently or is derived from a common precursor cell with migratory properties. Murine studies comparing newborn transplant outcomes before the onset of systemic circulation between the yolk sac site and the intraembryonic AGM site have emerged,[438] and these, together with the identification of placenta as an autonomous circulation-independent site with terminal erythroid maturation of primitive cells,[439] have added an additional layer of complexity.

A common precursor cell giving rise to erythroid cells with either yolk sac or fetal liver characteristics has been identified by culture of murine and human embryonic stem cells in vitro.[440,441] Environmental regulation of specification to the primitive or definitive lineage has been shown in *Xenopus*.[442] However, because BFU-E present in yolk sac, fetal liver, and fetal bone marrow have a definitive-like progeny and these progenitors were not present after ablation of core binding factor (CBF)-β[443] despite the presence of normal embryonic erythropoiesis, the derivation of embryonic erythroblasts from a distinct progenitor, not present in subsequent life, remains a viable hypothesis. Of further interest is the observation that deletion of Mdm2 and Mdm4, two critical negative regulators of p53, exerted distinct outcomes on primitive and definitive hematopoiesis. Whereas Mdm2 is required for primitive erythropoiesis, Mdm4 is required for massive

expansion of definitive erythropoiesis in fetal liver and is dispensable for adult erythropoiesis. These data are also consistent with the distinct molecular control between fetal and adult cells[444] discussed earlier.

TRANSCRIPTION FACTORS IN ERYTHROPOIESIS

Lineage-specific transcription factors are widely believed to be responsible for regulating the expression of erythroid genes during both ontogeny and the course of erythroid differentiation. The majority of erythroid-specific transcription factors has been identified from cloning of breakpoints or translocations associated with human leukemias or from expression libraries obtained from erythroid cell lines. The precise role exerted by each of these factors in erythropoiesis was later clarified by painstaking experiments with somatic cell fusions and in transgenic mice.[417,445,446] Some of the major transcription factors implicated in the control of erythropoiesis are listed in Table 24-2.

Studies of mice with targeted gene disruption have provided key insights into the complex molecular pathways that regulate hematopoiesis in general and erythropoiesis in particular.[1,2] These studies, complemented by in vitro differentiation of mutated embryonic stem cells into different lineages, have provided clear evidence about distinct regulatory requirements of primitive (yolk sac) versus definitive (fetal liver and bone marrow) erythropoiesis, or of early versus late stages of erythroid differentiation. Because erythropoiesis is the first differentiated lineage in embryonic yolk sac hematopoiesis and the predominant lineage in fetal liver hematopoiesis, factors that affect hematopoiesis in general will disturb erythropoiesis during early stages of development and lead to lethality at different gestational days, depending on the defect. The time in development at which disruption of each specific gene manifests its phenotype is used to establish a hierarchical control among the different transcription factors. The earliest disruption of erythroid differentiation is observed in mice lacking the bHLH factor TAL1/SCL, which is encoded by a gene initially identified on the basis of its localization in a chromosomal breakpoint region frequently associated with T-cell acute leukemia.[447] SCL^{null} embryos are bloodless and die very early, with abrogation of both yolk sac and fetal liver erythropoiesis.[448] Because of the requirement for SCL in the formation of the transcription complex with the nuclear protein Rbtn2/LMO2 rhombotin 2/LIM domain only 2 (Rbtn2/LMO2) and GATA1 (detailed later), it is not surprising that targeted disruption of Rbtn2 and LMO2 also produces a bloodless phenotype.[449]

Mice lacking expression of GATA2, a member of the GATA family of transcription factors, exhibit an early and severe quantitative defect in hematopoiesis that influences all lineages.[450] Other regulatory factors seem to totally spare embryonic (yolk sac) hematopoiesis and have a specific effect only on fetal liver hematopoiesis, with death occurring at later days (12.5 days post conception). In this category are the proto-oncogene c-Myb and the core-binding factors CBF-α_2/AML1 and CBF-β.[451-453] Embryonic erythropoiesis is spared in mice with targeted ablation of these genes. Both c-Myb, the cellular homologue of v-Myb proto-oncogene, and the heterodimeric transcription factor CBF are abundantly expressed early in normal myelolymphoid cells, with decreasing expression as differentiation proceeds. Their expression pattern and their functional influence on growth factor receptor genes (i.e., IL-3, GM-CSF, CSF1, T-cell antigen receptor [TCR] α, β) may underlie their importance in the development of all definitive hematopoietic lineages.[1]

Of paramount importance for adult erythropoiesis is the transcription factor GATA1, the founder of the GATA family of factors.[1] The GATA1 protein controls erythroid differentiation at several levels by controlling (in cooperation with GATA2) the proliferative capacity of erythroid progenitor/precursor cells, the apoptotic rate of erythroblasts, and the expression of lineage-specific genes. These effects are mediated through activation of expression of target genes by binding to specific sequences (WGATAR) present in the regulatory domains of virtually any erythroid gene, including EPOR and GATA1 itself. However, WGATAR binding sites also are present in genes specific for megakaryocytic, eosinophilic, mast cell, and dendritic lineages, as well as in genes expressed in testicular Sertoli cells. Insights into the specificity of GATA1 in erythroid differentiation have been provided by studies on the organization of WGATAR sites in erythroid-specific regulatory sequences. A minimal erythroid transcription-activation sequence that consists of a core-binding motif flanked by two canonical GATA1 binding sites has been identified. The core-binding motif is composed of one SCL binding site and one GATA binding site separated by 10 bp.[2] Different domains of the GATA1 protein are responsible for binding to the core and the flanking sequences. At least three functional domains in the GATA1 protein have been identified: two zinc finger domains (amino-terminal finger [NF] and carboxyl-terminal finger [CF]) and an active amino-terminal domain. The NF domain is required for association with Friend of GATA1 (FOG-1), a protein encoded by a gene identified using GATA1 as bait in the two-hybrid yeast assay.[454] FOG-1 contains 10 zinc finger domains, only the first of which is required for GATA1 binding. The function of its other 9 zinc finger domains is not clear because they appear to be dispensable in structure-function studies, but they are well conserved in evolution. The GATA1-FOG-1 heterodimeric complex binds to the two flanking sites of the minimal erythroid transcription activation domain. Experimentally induced genetic mutations, such as $GATA1^{V205M}$, impairing GATA1-FOG-1 interaction in mice lead to impaired megakaryocytopoiesis and absence of definitive erythropoiesis, whereas primitive erythropoiesis is normal.[455] Rescue experiments indicate that $GATA1^{V205M}$ newborns are severely anemic with anisocytosis and spherocytosis with striking reduction mainly in the expression of genes encoding membrane proteins, whereas expression of other erythroid-specific genes, such as Alas2, was not affected.[456] These results indicate that DNA binding of the GATA1-FOG-1 complex is necessary for activation of a subset of GATA1 target genes in definitive erythroid cells but is dispensable for their activation in primitive erythroblasts. It should be emphasized that GATA1-FOG-1 interaction, while activating the expression of erythroid genes, inhibits target gene activation in testicular Sertoli cells.[457] This result provides insight into how one factor regulates more than one differentiation program by suggesting that its function, but not its expression, is different depending on the cellular context. Whether GATA1-FOG-1 interaction inhibits erythroid gene expression in myelomonocytic cells has not been investigated.

The CF domain, on the other hand, recognizes and binds to the GATA site localized in the core of the minimal erythroid transcription sequence 10 bp downstream to the SCL binding site. SCL and GATA1 bind simultaneously to their respective sites of the core as multimeric complexes formed by SCL/E47/LMO2 on the one hand and by GATA1/LMO2 on the other. Binding of the two complexes to the core is stabilized by Lbd1, which forms a physical bridge between them. The paramount importance of the CF finger for GATA1 function is proved by the fact that GATA1 genes lacking the region encoding this domain are unable to rescue erythroid differentiation in $GATA1^{null}$ embryonic stem cells,[458] whereas minigenes containing only the CF of either GATA1 or GATA2 are sufficient to induce megakaryocytic differentiation of myeloid cell lines.[459] In addition to forming heterodimers with LMO2, CF can form complexes with Sp1 and PU.1, two factors essential for myelomonocytic differentiation. The GATA1-PU.1 complex is unable to bind DNA, so its function might be to establish either an erythroid- or a myeloid-permissive cellular environment depending on which factor is expressed at the highest concentration.[2] The presence of relatively higher concentrations of GATA1 would favor the formation of GATA1-LMO2 complexes leading to activation of erythroid-specific genes, whereas the presence of relatively higher concentrations of PU.1 would lead mainly to the formation of the transcriptionally inactive GATA1-PU.1 complexes.

Although early experiments on cell lines failed to identify any function for the amino-terminal domain of GATA1,[459,460] knock-in experiments in mice indicated that this domain, although dispensable for primitive erythropoiesis, is required for appropriate production of definitive red cells.[458] A truncated GATA1 gene lacking the amino-terminal domain is 10 times less efficient than the full-length gene

in rescuing erythroid differentiation in GATA1^{null} mice.[458] This experiment suggests that interaction of the amino-terminal domain of GATA1 with a suitable partner(s) is required for optimal definitive erythropoiesis. Structure function studies have identified that interaction between the amino-terminal domain of GATA1 and the product of the retinoblastoma (RB) gene is essential for proper terminal erythroid maturation, providing a unifying mechanism for the similar phenotype of several Gata1 and RB mouse mutants and of human diseases associated with mutations in these two genes.[461]

In addition to all the evidence pointing to GATA1 as exerting a predominant but ontogenetic-specific role in the control of erythroid differentiation, other evidence indicates that this gene exerts exquisite control in the differentiation of other hemopoietic lineages, such as megakaryocytes,[1] mast cells,[462] eosinophils[463] and dendritic cells.[464] The mechanism used by one single factor in guiding differentiation along different lineages does not rely on specific domains in the GATA1 protein itself. In fact, the structure of all the GATA proteins is so well conserved among different family members and in evolution that GATA1^{null} embryonic stem cells are rescued not only by reintroduction of the GATA1 gene itself but also by introducing any other member of the GATA family, such as GATA3.[465] The lineage-specific action of GATA1 in regulating gene expression is achieved through the presence of lineage-specific regulatory sequences in the promoter regions of the target genes. Therefore the relative concentration of GATA1, as opposed to the levels of a few key regulatory partners, may establish a lineage-permissive microenvironment. Furthermore, the existence of lineage-specific regulatory sequences in the GATA1 gene itself ensures that such concentrations are achieved only in the right cell. Although GATA1 is expressed in erythroid, megakaryocytic, mast, dendritic, and eosinophilic cells, its level of expression differs greatly among the various cell types, with erythroid cells expressing the most. Three DNase hypersensitive sites (HS) have been recognized within the 8 Kb upstream and the first intron of the murine GATA1 gene, defined as HSI, HSII, and HSIII. Targeted deletion mutants in the mouse have shown that each of these sites functions as an enhancer in different cell types. HSI is required for GATA1 expression in megakaryocytes,[466] mast cells,[462] and also for upregulation of GATA1 expression during the process of antigen presentation in dendritic cells[467] and during the progression of erythroid maturation.[468] HSIII is capable of sustaining low levels of GATA1 expression in erythroid and dendritic cells. HSII, which is dispensable for erythroid and megakaryocyte expression, is absolutely required for gene expression in eosinophils.[463] All of the 317 bp of HSI are required for GATA1 expression in megakaryocytes, but only the first 5′ 62 bp are needed for erythroid-specific reporter activity.[469] The HSI region contains a canonical minimal erythroid activation sequence, and point mutations in the GATA site, but not in the E-box, abolish HSI function in both erythroid and megakaryocytic cells. Of note, GATA1 mRNA has an unusually long half-life (>9 hours). Two GATA1 bands, corresponding to the native and processed (acetylated and phosphorylated) forms of the protein, have been detected by Western blot analysis.[470] The processed form binds DNA with higher affinity than the native form. Furthermore, although the half-life of the native form is short (approximately 0.5 hour) and stabilized by EPO, the processed form is extremely stable (half-life >6 hours) and EPO independent.[470] Because the cell cycle of hemopoietic cells in vivo is as short as 6 hours, erythroid cells accumulate GATA1 mRNA and protein as they proliferate. Because maturation is dependent on the levels of GATA1 expressed by cells, the cellular GATA1 content might represent the biologic clock that, by controlling the number of precursors, determines the cellular output of the differentiation process. This hypothesis suggests that EPO-induced GATA1 processing through the ubiquitin-proteasome pathway is an important element in the regulation of erythroid differentiation. On the other hand, the TRAIL–Bruton kinase death pathway has as an end point caspase 3, the protein specifically responsible for GATA1 cleavage. However, caspase 3 is unable to cleave GATA1 if the protein is complexed in the nucleus with the chaperone protein heat shock protein 70 (Hsp70). EPO-receptor signaling counteracts the apoptotic pathway by favoring Hsp70-GATA1 colocalization in the nucleus.[471] The equilibrium between TRAIL and EPO-dependent control on Hsp70 localization may be perturbed under pathologic conditions. As an example, defective nuclear localization of Hsp70 and increased GATA1 cleavage is associated with dyserythropoiesis in myelodysplastic disorders.[472] These biochemical studies detailing the biochemical link between EPO and TRAIL from one side and GATA1 from the other are consistent with studies indicating that EPO signaling also induces GATA1 phosphorylation at Ser310 and that this phosphorylation plays an important role in regulating GATA1 function in erythroid cell lines.[473,474] Although GATA1 mutants expressing only the native form of GATA1 do not have a detectable erythroid phenotype under steady-state conditions,[475] more studies on the response of these mice to erythroid stress will clarify the role of GATA1 processing in stress erythropoiesis.

Another gene of the GATA family important for erythroid differentiation is GATA2. Both GATA1 and GATA2 are expressed early in multipotential progenitors; however, their expression ratios change as the cells differentiate (see Table 24-1),[476] suggesting that the ratio of these two factors may be important at specific stages of erythroid differentiation. Knock-out experiments with both of these genes have borne this out. Thus in contrast to GATA2, which is expressed at high levels in early cells and affects expansion of all hematopoietic lineages,[450] GATA1 expression increases as differentiation advances and seems to be the obligatory factor required for survival and terminal differentiation of erythroid cells. In mice with targeted disruption of GATA1, erythropoiesis proceeds only up to the stage of proerythroblasts; these mice die early and fail to mature further.[477,478] Furthermore, transgenic mice with partial loss of function (knockdown alleles, GATA1^{LOW}) of GATA1 show that erythroid differentiation is dose dependent with respect to GATA1.[468] High levels of GATA1 are necessary to form complexes with its cofactor FOG-1[454] and with the other proteins described earlier (LM02, SCL, or Hsp70) during terminal erythroid differentiation.

The realization that minute differences in transcription factor concentrations are required for lineage specification under physiologic conditions supports the idea that the differentiation system allows more flexibility in both the choice and the reversibility of pathway commitment toward a specific lineage. For example, a CFU-E was thought to have no other choice than to became an erythroid cell or to die.[6] More recently, experiments with forced expression of transcription factors in fully committed or even mature cells have demonstrated that the system has some degree of plasticity and that forced expression of FOG-1 into mast cells may turn them into erythroblasts,[479] whereas forced expression of GATA1 into common myeloid progenitor cells induces their transdifferentiation into MEP.[480] It is foreseen that future experiments will demonstrate that any cell type may be turned into an erythroblast by overexpression of an appropriate combination of transcription factors. All of these manipulations were performed in vitro. Of interest, experimentally decreased expression of GATA1 in progenitor cell compartments in vivo does not alter the frequency of individual compartments (i.e., does not decrease MEP by increasing the granulocyte/macrophage progenitor) but results in alternative differentiation pathways. Although the numbers of cells phenotypically recognizable as MEP in these animals are much higher than normal, MEP with reduced GATA1 expression, unlike normal cells, have the potential also to differentiate into mast cells.[481]

Another factor with special importance in the erythroid lineage is the CACCC binding protein designated EKLF (also known as KLF1), which is expressed at all stages of erythropoiesis but binds preferentially to CACCC sites in the β-globin promoter. EKLF is a zinc finger protein that binds not only DNA, but also, after appropriate posttranslational modifications, is a key regulatory protein that modulates chromatin structure of the β-globin locus.[482] Mice lacking EKLF (EKLF^{null}) die of a thalassemic-like defect due to severe deficiency of β-globin expression.[483] Microarray analysis of EKLF^{null} erythroid cells and promoter-specific expression of reported genes in EKLF^{null} cells have identified that the first GATA1-dependent molecular control of erythroid differentiation is followed by a second EKLF-dependent phase.[484,485] Primarily GATA1-dependent genes

include, in addition to *EPOR* and those involved in the control of apoptosis, α- and δ-globin. EKLF-dependent genes, in addition to β-globin[486,487] and AHSP, are represented by those required for appropriate membrane assembly, such as β-spectrin, ankyrin, and band 3 (but not α-spectrin). These results are consistent with the notion that, in erythroid differentiation, activation of α-globin gene expression precedes that of β-globin[488] and that loss of GATA1 binding sites in the promoter of the gene is found in α-thalassemia,[489] in the Greek nondeletion HPFH (guanine to adenine at nucleotide position-−117 of γ-globin),[490] and in δ-thalassemia (point mutation leading to G→A substitution at position +69 of the δ-globin gene),[491] whereas loss of EKLF binding site is present in other forms of HPFH. In addition to regulating globin gene expression directly, EKLF inhibits γ-globin expression indirectly by activating BCL11A expression.[492]

Intrinsic control of erythroid differentiation also is exerted by genes that, until repressed, prevent terminal cell maturation. The most studied of these genes is ID1,[493] which as its name indicates, inhibits differentiation along almost all mesenchymal cell lineages, including the erythroid lineage.[494,495] ID1 appears to act between GATA1 and EKLF by preventing EKLF from executing its program.

Because common transcription factors are present in erythroid and megakaryocytic cells, and bipotent erythroid/megakaryocytic progenitors exist both in vitro (in the form of cell lines) and in vivo,[56] exciting insights regarding subtleties in the molecular control of these two lineages by the same transcription factors have surfaced. Modified gene–targeting strategy ("knockdown") of GATA1 uncovered a largely unanticipated role of this transcription factor in the control of proliferation and maturation of megakaryocytes.[468] In addition to GATA1, other important transcription factors essential for terminal megakaryocytic development are NF-E2[496] and its partner mafG.[497]

Nevertheless, the fact that several regulators are necessary for primitive (yolk sac), as opposed to definitive (fetal liver and bone marrow), erythropoiesis provides evidence that molecular control between these two hemopoietic sites is different and may include both ubiquitous and hematopoietic-specific factors. In fact, evidence suggests that GATA1 transcription is differentially regulated in yolk sac cells compared to fetal liver erythroid cells, with alternative promoter use and an additional intron element requirement for promoter activation in fetal liver cells.[498]

In addition to transcription factors/oncogenes influencing erythropoiesis, targeted ablation and naturally existing mutations of hematopoietic growth factor receptors, especially of the tyrosine kinase family, have disclosed important insights into the control of erythropoiesis. Whereas deletion of the vascular endothelial growth factor (VEGF)/flk-1 receptor affects both endothelial and hematopoietic development[499] through its presumed presence in the hemangioblast, the common endothelial/hematopoietic stem cell, mutations affecting the tyrosine kinase KIT receptor (present in hematopoietic cells) or of its ligand KL (present in stromal cells) seem to predominantly affect erythropoiesis in the fetal liver and the adult animal. Mice with KIT mutations (W mutations) leading to absence of or compromised kinase activity and steel mice with mutations of KL have disproportionate and severe reduction of the numbers of late erythroid progenitors, CFU-E, and differentiated erythroid precursors resulting in anemia.[500] Studies showing cross-phosphorylation of EPOR following activation of KIT/KL signaling may be relevant to the effect.[277] Mutations or targeted ablations of some downstream signaling substrates for KIT or other receptors (i.e., SHP2 phosphatase or gp130) seem to produce a hematopoietic picture not unlike the one produced by receptor mutations.[501,502]

Taken together, these studies have significantly expanded our understanding of the molecular basis of hematopoietic cell development in general and of erythropoiesis in particular. The emerging picture is that certain genes, such as SCL, are absolutely required for hematopoietic development, whereas other genes, such as GATA2, c-Myb, CBF, TEL, and some downstream signal transducing molecules, such as gp30 and SHP2, are responsible for expansion and maintenance of a normal pool of fetal liver and adult hematopoietic progenitors. The participation of many of these molecules in multicomponent molecular complexes with protein/protein and protein/DNA interactions (i.e., LM02/Lbd1/SCL/E2A/GATA), during the early proliferative stages of hematopoiesis[503] may underlie their role in the proliferation and maintenance of immature progenitor/precursor pools in erythropoiesis. Other genes such as GATA1, its partner FOG-1, and EKLF are necessary to direct high levels of function of erythroid-specific genes in cells already committed to terminal differentiation. Thus a hierarchical requirement in the expression of specific regulators during early versus late erythroid differentiation or during yolk sac versus fetal liver/adult erythropoiesis is demonstrated. However, this does not exclude the involvement of some factors (i.e., SCL, TEL) at both early and late stages of erythropoiesis. In fact, more recent studies on conditional knockouts have clarified that SCL exerts two different levels of control in the development of the hemopoietic system. First, SCL is required for the determination event that induces one (or few) mesenchymal cell(s) to become a hematopoietic stem cell(s) in the early embryos.[181] After this initial event has taken place, its presence becomes dispensable, as demonstrated by the fact that conditional SCL deletion in the adult animals impairs only erythropoiesis and megakaryocytopoiesis.[181,504]

With information from innovative applications of molecular approaches becoming available at a fast pace, the list of regulators with a biologic impact on hematopoiesis/erythropoiesis not only is continuously expanding but is starting to fill the gap between the individual transcription factors and the epigenetic control of erythroid cells. Actively expressed genes are localized in areas on the chromosome in an open configuration. The DNA switch from a closed to an open configuration is determined by the tightness of its binding to the histones by which it is surrounded.[505] A series of enzymes regulates the chromosome configuration state by modifying either the DNA (cytosine methylation mediated by specific methylases) or the histones (e.g., histone acetyltransferase [HAT] and deacetylase [HDAC], polycomb repressive complexes). HAT exerts a positive control (promoting the formation of an open configuration state), whereas methylases and HDAC exert a negative control (inducing a closed chromatin configuration state) on gene expression. Once the chromatin is in an open configuration state, appropriate enzymatic complexes (e.g., polymerases, spliceosomes) are recruited to the locus for appropriate expression to occur. Because of their ability to recognize specific DNA sequences, transcription factors play an important role in the recruitment of the epigenetic and/or transcriptional protein machinery to a specific locus. The link between epigenetic and transcriptional control of gene expression in erythroid cells is emerging. The first global methylation status of erythroid cells as they mature has been determined.[506] The relationship between chromatin architecture and transcription factor occupancy in the loci encoding key erythrocyte membrane proteins has been established.[507] In addition to binding GATA1, FOG-1 is also capable of binding NuRD, a complex that contains HDAC1.[508] The multicomplex GATA1/FOG-1/NuRD is responsible for appropriate activation/repression of several erythroid specific genes, including the GATA2-GATA1 switch occurring at early stages of erythroid development.[509]

TRANSCRIPTIONAL AND POSTTRANSCRIPTIONAL IMPAIRMENT IN DISORDERS OF ERYTHROPOIESIS

The transcription factor found most frequently altered in inherited and acquired human diseases of the erythroid and megakaryocytic lineage is GATA1. The mutations often involve the region of the gene encoding the NF domain. Mutations in the GATA1 NF domain interrupting its interaction with FOG-1, such as V205M and G208S, are responsible for familial dyserythropoietic anemia and X-linked thrombocytopenia, respectively.[510,511] A different mutation at position 208 leading to G→A substitution is associated with dyserythropoietic anemia and macrothrombocytopenia.[512] Mutations in the NF terminal domain of GATA1 responsible for DNA binding, such as A216G[513] and D218G,[514] instead have been found to be associated with X-linked thalassemia and/or thrombocytopenia. The phenotype of X-linked thrombocytopenia was mimicked in mice by knock-in experiments of the mutant V205G GATA1 gene.[515] However, the

same A216G mutation has been found associated with X-linked gray platelet syndrome, a mild bleeding disorder characterized by thrombocytopenia and large agranular platelets.[516] Furthermore, a mutation at codon 216 changing arginine to tryptophan (R216W) was detected in a 3-year-old boy with congenital erythropoietic porphyria, an autosomal recessive disorder usually due to mutations of the uroporphyrinogen III synthase gene (UROS). The boy also presented with microcytic anemia and red cell morphologic characteristics and a globin chain pattern compatible with β -thalassemia and increased HbF levels (59.5%).[517] The different phenotype expressed by patients carrying mutations either in the FOG-1 or the DNA binding portion of NF supported the notion that the two domains influence erythroid versus megakaryocytic maturation.[518] However, the observation that, in certain cases, a mutation in the same codon or even the same mutation results in a different phenotype suggests that the phenotype induced by mutations in the GATA1 gene is extremely sensitive to genetic modifiers outside the GATA1 locus. This hypothesis has been demonstrated in mice in which the same mutation induces embryonic lethality, thrombocytopenia, or myelofibrosis, depending on the mouse background in which it is harbored.[519]

On the other hand, frameshift and splice mutations encoding GATA1s, a protein lacking the amino-terminal domain, not only are associated with impaired erythropoiesis[520] but also are found in patients with megakaryocytic leukemia in Down syndrome,[521,522] in newborns with transient myeloproliferative syndromes,[523] and in one adult patient with megakaryocytic leukemia.[524] A mutation equivalent to that found in patients with acute megakaryoblastic leukemia and Down syndrome was created in mice by *N*-ethyl-*N*-nitrosourea mutagenesis screening. The reduced expression of the full-length GATA1 was not compensated in mice by expression of GATA1s. The mutation was embryonic lethal in hemizygous males and induced thrombocytopenia in heterozygous females.[525] However, when introduced in mice the GATA1s mutation increased proliferation of a "unique" fetal stem/progenitor cell extinguished in adult life.[526] The association between a mutation of GATA1 and the development of leukemia supports the concept that GATA1 controls the proliferation of hematopoietic progenitors. Reduced GATA1 expression, by increasing progenitor cell proliferation, may predispose hematopoietic cells to leukemia by favoring accumulation of secondary mutations. These mutations may involve the GATA1 itself because transforming Myb-GATA1 fusion genes have been associated with reduced GATA1 levels in acute basophilic leukemia.[527,528] Alterations of hematopoietic proliferation appear to be achieved through quantitative, rather than structural, GATA1 alterations. The GATA1s protein is far less efficient than the full-length GATA1 in rescuing the phenotype of GATA1^{null} embryonic stem cells,[458] and hypomorphic mutations in mice induce either leukemia[529] or a phenotype similar to idiopathic myelofibrosis,[530] depending on the severity of the reduction of the expression. Interestingly, the reduced content of GATA1 in megakaryocytes, through an as yet unidentified molecular defect rather than the presence of JAK2V617F, distinguishes primary myelofibrosis from all the other myeloproliferative neoplasms in humans.[531] (For a more complete review on the role of GATA factors in hematologic diseases, see reference 532.)

Point mutations in the EKLF/KLF1 gene have been associated with human diseases of terminal erythroid maturation (see Table 24-2). E325K substitution in the conserved residue of the zinc finger domain 2 is associated with congenital dyserythropoietic anemia.[533,534] Premature stop codons (L127X, K292X), point mutations in conserved residues of the zinc finger 1 (H299Y) and 2 (R328L, R328H, R331G), frameshift (X47 and X34), and hypomorphic mutations (deletion of the GATA1 binding site in the promoter region) have been associated with lack of Lutheran group antigen (Lu negative phenotype),[535] whereas neutral substitution (M39L), premature stop codon (K288X), and premature stop codon plus point mutations in the conserved residue of zinc finger 2 (S270X plus K332Q) have been associated with the HPFH phenotype with or without elevated zinc protoporphyrin.[425,427] Hereditary spherocytosis has also been observed in mice carrying the spontaneous Nan mutation (E339D substitution in the conserved residue of zinc finger 2).[536]

Another disease associated with abnormalities in the molecular machinery of red cell differentiation is represented by DBA, a rare congenital red cell hypoplasia characterized by anemia, bone marrow erythroblastopenia (lack of late erythroid forms), and congenital anomalies. The disease is associated with heterozygous mutations in the ribosomal protein S19 gene (RPS19) in approximately 25% of probands.[537] In a large cohort of 172 new families with familial history of DBA, mutations affecting the coding sequence of RPS19 or splice sites were found in 34 cases (19.8%), whereas additional mutations in noncoding regions were found in 8 patients (4.6%). Mutations included nonsense, missense, splice site, and frameshift mutations. More recently, de novo nonsense and splice-site mutations in another ribosomal protein, RPS24 (encoded by RPS24 [10q22-q23]), was identified in approximately 2% of RPS19 mutation-negative probands.[538] The molecular defect of the other families is yet to be uncovered. No correlation between the nature of mutations and the different patterns of clinical expression, including age at presentation, presence of malformations, and therapeutic outcome, has been documented. The lack of a consistent relationship between the nature of the mutations and the clinical phenotype implies that as yet unidentified factors modulate the phenotypic expression of the primary genetic defect in families with RPS19 mutations.[539] Two not mutually exclusive hypotheses had been proposed to explain the pathobiologic role of RPS19 (and RPS24) in the pathogenesis of the disease: (1) loss of unknown functions not directly connected with RPS19's structural role in ribosomes and (2) altered protein synthesis because of poor ribosome organization. The first hypothesis was suggested by findings based on a proteomic approach that identified numerous proteins bound to RPS19. In addition to FGF2, complement component 5 receptor 1, a nucleolar protein called RPS19 binding protein, and Pim-1, the other RPS19-binding proteins fall in the following Gene Ontology categories: NTPases (ATPases and GTPases; 5 proteins), hydrolases/helicases (19 proteins), isomerases (2 proteins), kinases (3 proteins), splicing factors (5 proteins), structural constituents of ribosome (29 proteins), transcription factors (11 proteins), transferases (5 proteins), transporters (9 proteins), DNA/RNA-binding protein species (53 proteins), other (1 dehydrogenase protein, 1 ligase protein, 1 peptidase protein, 1 receptor protein, 1 translation elongation factor), and 13 proteins with unknown function.[540] However, more recent studies have identified that RPS19 plays an essential role in the biogenesis and maturation of the 40S small ribosomal subunit in human cells[541,542] because of reduced gene expression of clustered ribosomal proteins due to abnormal pre-mRNA processing.[543] Such a defective ribosomal gene expression results in alterations of the transcription, translation, apoptosis, and oncogenic pathways.[544] Expression of RPS19 mRNA and protein decreases during terminal erythroid differentiation.[545] A mouse model of the disease has been generated by disrupting the endogenous Rps19 gene.[546-548] Cellular models of the disease have been established by small interfering RNA (siRNA) technology against RPS19 protein.[549-551] These models are establishing that RPS19 deficiency is accompanied by an unanticipated activation of p53 and death of the erythroid cells. Treatment of RPS19^{null} cells with dexamethasone prevents p53 activation and restores terminal erythroid maturation,[552] providing a molecular mechanism for the therapeutic effects exerted by dexamethasone in these patients. Alternatively, it has been proposed that dexamethasone may rescue defective protein synthesis in ribosomal-deficient erythroid cells by increasing expression of a subset of GR target genes (such as Zfp36l2, which controls RNA stability and/or translation).[553] Only 40% to 50% of DBA patients respond to steroids.[554] The mechanism underlying this lack of response has been the subject of recent investigation. The increased frequency of rs6198 GR SNP observed in these patients suggests that the failure to respond to steroids may be influenced by genetic and/or epigenetic modifications of the GR locus.

RSP19 deficiency and p53 activation is also observed in the 5q− MDS syndrome,[552] and p53 activation associated with reduced ribosomal gene dosage has been reported in low-risk MDS.[555] Whole-exome sequencing of MDS has recently uncovered mutations in genes involved in RNA splicing.[556,557] Whether these mutations also activate

p53 has yet to be determined. These results suggest that defective mRNA splicing/translation may represent a unifying mechanism for the etiology of MDS. Interestingly, MDS has also been associated with mutations in GATA2. In fact, in spite of its importance in the early phases of erythroid maturation, GATA2 mutations have not been detected in erythroid diseases so far. However, a gain-of-function GATA2 mutation has been reported in one patient with chronic myelomonocytic leukemia[558] and loss-of-function GATA2 mutations have been systematically detected in patients with a rare genetic immunodeficiency distinguished by reduced levels of all the immune cells produced in the marrow (monocytes, dendritic, NK and B cells, MonoMAC syndrome)[559,560] (see Table 24-2). The marrow of these patients is hypocellular, with absent/reduced levels of multilymphoid and myeloid progenitor cells and dysplasia of the myeloid as well as the erythroid and megakaryocytic lineage. These patients may eventually develop MDS and AML. Mutations in the coding region of GATA2 have also been found in four patients with MDS without immunodeficiency.[561] In addition, quantitative alterations (reduced levels) in GATA2 expression, possibly secondary to the primary lesions, have been described in the $CD34^+$ cells from patients with aplastic anemia[562] and in blasts from AML,[563] and although hypomorphic GATA2 mutations do not induce a strong phenotype in mice,[561] genome-wide analyses of transcriptional reprogramming of mouse models of AML have identified GATA2 as one of the few key transcription factors whose expression is reduced in leukemic blasts.[563]

CELLULAR DYNAMICS IN ERYTHROPOIESIS

The primary function of the mature red cell, which is the end product of erythropoiesis, is to transport oxygen efficiently through the circulation to the tissues. To achieve this goal, the adult marrow must release approximately 3×10^9 new red cells, or reticulocytes, per kilogram per day.[564] This number of reticulocytes represents (1%) of the total red cell mass and is derived from an estimated 5×10^9 erythroid precursors per kilogram.[564] In addition to maintaining homeostasis (i.e., a stable hematocrit), the erythron must be able to respond quickly and appropriately to increased oxygen demands, either acute (e.g., following red cell loss) or chronic (e.g., with hypoxia from pulmonary disease or a right-to-left cardiac shunt). It is well established that EPO is responsible both for maintaining normal erythropoiesis and for increasing red cell production in response to oxygen needs. However, the overall marrow response is complex and requires not only the participation of erythroid cells responsive to EPO but also a structurally intact microenvironment and an optimal iron supply within the marrow.

EPO stimulation elicits two types of measurable responses: changes in proliferative activity (including improved survival) and changes in maturation rates. The first detectable response to increased serum EPO is amplification of CFU-E and erythroid precursors, cells that are extremely sensitive to EPO. Because virtually all these cells are already in cycle, increases in their numbers cannot be achieved by increasing their fraction in cycle. Either additional divisions are involved, or new cells are recruited to the CFU-E pool (from a pre-CFU-E pool). Additional divisions of CFU-E or precursor cells would increase their transit time within the marrow and potentially delay the delivery of new red cells to the periphery. Because a shortened maturation time has been observed instead and the proliferative potentials of CFU-E and proerythroblasts are finite, high levels of amplification cannot be achieved through this mechanism. Therefore such needs are met by influx into the CFU-E and precursor pools of newly differentiating cells from earlier progenitor compartments.

Such a surge of newly produced cells has been observed in prior experiments.[188,565,566] A rapid influx of fresh cells was particularly notable in polycythemic mice that were experimentally depleted of CFU-E and erythroid precursors at the time the stimulus was applied.[160,188] Because of the rapidity of response (i.e., within 24 hours in the polycythemic animals), it appeared that the orderly progression from BFU-E to CFU-E to proerythroblast had been compressed. Such acceleration of differentiation is possible through shortened intermitotic intervals, fewer mitotic divisions, or differentiation without divisions. This short-circuiting in differentiation requires high serum levels of EPO and adequate numbers of BFU-E (i.e., these conditions are met in a previously hypertransfused, polycythemic animal stimulated by EPO or in marrow suddenly recovering from acquired pure erythroid aplasia). Once CFU-E and precursors are expanded through this mechanism, most persisting erythropoietic demands can be met through this pool without excess input from pre-CFU-E pools. Thus acute demand for erythropoiesis is met by influx from pre-CFU-E pools through an accelerated differentiation and maturation sequence. In contrast, chronic demands (i.e., demands due to a chronic hemolytic anemia) are mainly satisfied through a greatly amplified late erythroid pool and with a minimum distortion in the differentiation sequence.[142,567] The fact that the kinetics of erythroid differentiation/maturation are different in acute versus chronic marrow regeneration is supported by differing qualitative changes in the newly formed red cells. An increase in i antigen and HbF expression as well as an increase in cells with higher mean corpuscular volumes is seen with an acute response, whereas these alterations are minimal or less pronounced with chronic responses.[142,568] When severe anemia persists from birth onward, erythroid production can increase up to 10-fold above baseline.[567] This is possible not only because of maximally expanded erythropoietic pools but also because the sites of active erythropoiesis may extend to include those that support red cell differentiation during fetal life. Thus although the marrow space in axial bones (vertebrae, pelvis, ribs, sternum, clavicles) is sufficient for normal erythropoiesis or for response to moderate anemia, the femur, humerus, spleen and/or liver, and (rarely) thymus may support red cell production in children with congenital hemolytic anemia (e.g., thalassemia major). Expanded erythropoiesis may lead to skeletal deformities, hepatosplenomegaly, or erythropoiesis in the soft tissues adjacent to bone.

Quantitative assessments of changes in erythroid progenitor cell pools in response to EPO stimulation can be made through cultures of bone marrow cells. Despite sampling errors, erythroid cultures can provide rough estimates of relative progenitor abundance within an aspirated marrow specimen and have shown consistent increases in the frequency of CFU-E in proportion to the level of EPO stimulation.[569,570] Conversely, with increases in the hematocrit or in polycythemic animals, a decrease in CFU-E frequency has been observed.[571,572] In contrast to CFU-E, the incidence of BFU-E was found to fluctuate less with either acute or chronic expansion of erythropoiesis, probably because a few BFU-E can generate several thousand cells. Furthermore, BFU-E can increase their fraction in cycle and thus increase the number of differentiated progeny without a significant change in their total numbers. Most BFU-E detectable in marrow or blood erythroid cultures probably represent a reservoir of progenitors not normally participating in day-to-day erythropoiesis. The parameters needed to maintain a healthy or appropriate BFU-E pool in hematopoiesis are not defined. That hematopoietic expansion is curtailed in mice with steel mutations and anemia develops in mice treated with anti–C-KIT antibody[573] suggests that adequate levels of normal KL may be crucial for early erythropoietic expansion.[189]

The rate of red cell production also can be accurately evaluated by ferrokinetic studies (i.e., study of iron incorporation into developing red cells). In addition, a marrow scan, typically with technetium Tc 99m, can document the extent of active erythropoiesis. However, these approaches seldom are necessary in clinical practice because estimates of erythropoiesis can be obtained from the reticulocyte index.[567] First, the observed percentage of reticulocytes is normalized to the hematocrit to calculate the total marrow output of reticulocytes. Alternatively, the absolute number of reticulocytes per microliter can be counted directly using fluorescent RNA labeling. However, because younger reticulocytes are prematurely released into the circulation under conditions of acute need, the total number of reticulocytes overestimates the true level of red cell production as measured by iron kinetics.[567] Therefore a second correction is made to account for the maturation of early circulating reticulocytes, or "shift" cells

(polychromatophilic red cells), when present in the blood smear. The resulting reticulocyte index gives excellent estimates of effective red cell production.

Although the presence, density, or both of EPORs on developing erythroid cells determines the responses to EPO, other properties (e.g., surface antigens on BFU-E versus CFU-E versus end-stage red cells) may provide the basis for selective suppression of CFU-E versus BFU-E or selective immune destruction of red cells versus erythroblasts. For example, suppression of CFU-E or erythroblasts can occur in acquired pure red cell aplasia[574] or B19 parvovirus infection,[575] respectively, whereas BFU-E in both these conditions remain largely unperturbed. Thus the boundary from BFU-E to CFU-E and erythroblast may be biologically important for the pathophysiology of these disease states. Furthermore, in acquired hemolytic anemia, selective destruction at a given stage of maturation (of red cells only or of both erythroblasts and red cells) can be observed depending on the type of antibody produced and the density of its antigen on maturing erythroid cells. Qualitative aberrations in the response of erythroid progenitors to cytokines or EPO may underlie the abnormalities of congenital erythroid hypoplasia (Diamond-Blackfan syndrome).[361] Analogous qualitative or functional defects can be observed in neoplastic erythropoiesis, because erythroid progenitors from patients with polycythemia vera and other myeloproliferative neoplasms have altered sensitivities to EPO.[576]

Detailed knowledge of the structural and functional properties of erythroid cells throughout their differentiation may provide significant insights into the pathogenesis of hematopoietic disorders affecting the red cell lineage.

CHAPTER 25

GRANULOCYTOPOIESIS AND MONOCYTOPOIESIS

Arati Khanna-Gupta and Nancy Berliner

GRANULOCYTOPOIESIS

Granulocytes (neutrophils, eosinophils, and basophils) are short-lived cells that are critical to both antimicrobial and inflammatory responses. The bone marrow (BM) produces granulocytes, especially neutrophils, at a prodigious rate to supply the baseline needs of circulating cells that survive in the peripheral blood for only 3 to 6 hours. It also has the capacity to upregulate granulocyte production sharply in response to a wide range of stresses. The regulation of granulocyte production is controlled by a variety of cytokines that induce the myeloid differentiation program through the carefully orchestrated interaction of multiple general and myeloid-specific transcription factors. Understanding this intricate maturation sequence provides important insights into normal neutrophil responses to infectious, inflammatory, and allergic stresses, as well as into the dysregulation of differentiation contributing to the origins of myelodysplasia and leukemia.

Granulocyte Ontogeny

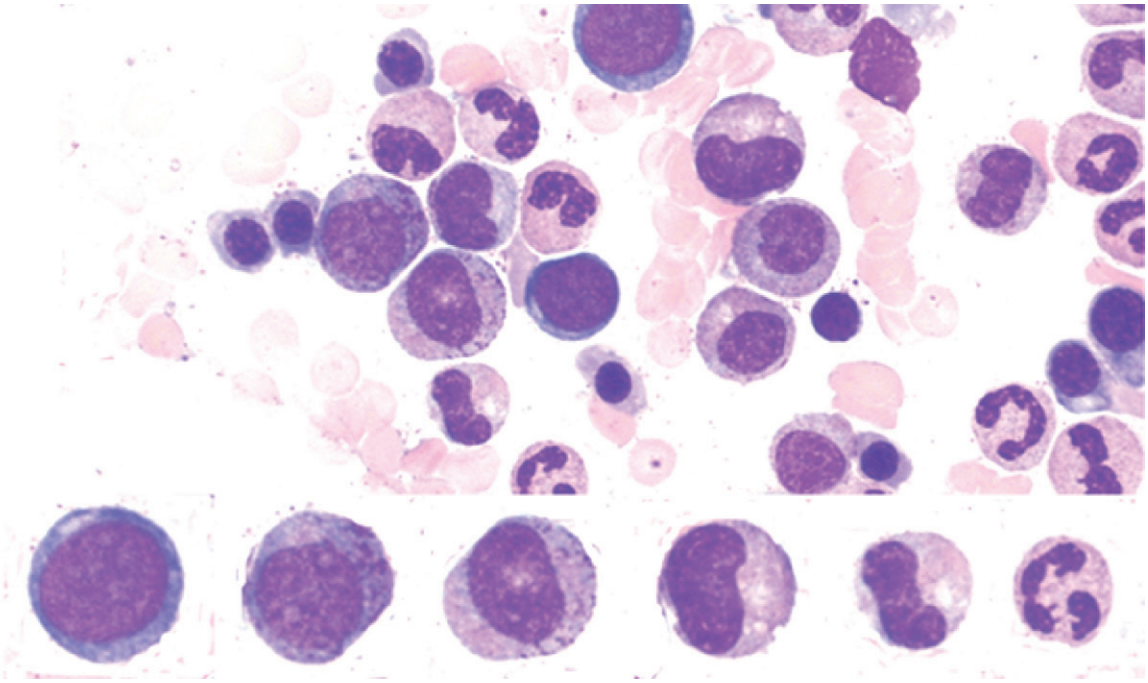
Stages of Neutrophil Differentiation

Granulocytes differentiate from early progenitor cells in the BM in a process that takes 7 to 10 days. The cells pass through several identifiable maturational stages, during which they acquire the morphologic appearance and granule contents that characterize the mature granulocyte.[1] The earliest identifiable granulocyte precursor is the myeloblast, a minimally granulated cell with scant cytoplasm and a prominent nucleolus (Fig. 25-1). Transition to the promyelocyte stage is associated with the acquisition of abundant primary granules. Primary granules are found in both granulocytes and monocytes and contain many of the proteins necessary for intracellular killing of microbes. The transition to the myelocyte stage is associated with the acquisition of secondary or "specific" granules, which give the characteristic staining that differentiates neutrophils from eosinophils and basophils.

Neutrophil precursors account for approximately half of the cells in the marrow of normal persons, with a majority at the metamyelocyte stage and more differentiated forms. Promyelocytes and myelocytes represent the primary proliferative pool of granulocyte precursors in the BM. Beyond the myelocyte stage, cells mature as nondividing cells. Bands and segmented neutrophils constitute greater than 50% of the total granulocyte mass, primarily as a mobilizable pool of cells in the BM. Only 5% of total neutrophils circulate in the periphery, where 60% are marginated in the spleen and on vessel walls. Mature neutrophils circulate in the peripheral blood for 3 to 12 hours and then migrate to the tissues, where they survive 2 to 3 days. Hence, the peripheral blood count reflects roughly 2% of the total neutrophil cell mass spanning approximately 1% of the neutrophil lifespan.

Biochemical events that accompany these physical changes include the sequential acquisition of primary granules and their content proteins (e.g., myeloperoxidase, lysozyme, neutrophil elastase [NE, also known as ELANE], defensins, myeloblastin), secondary granules and their content proteins (lactoferrin, neutrophil collagenase matrix metalloproteinase 8 or MMP-8), neutrophil gelatinase [MMP-9], neutrophil gelatinase-associated lipocalin [NGAL], transcobalamin 1), and tertiary granules containing neutrophil gelatinase (Table 25-1). The progressive gain of characteristics of differentiated cells is accompanied by a loss of proliferative potential. This carefully coordinated process is disrupted in acute myeloid leukemias (AMLs), in which a block in the myeloid maturation pathway usually results in the circulation of immature blasts in the peripheral blood.

Markers of Granulocytic Maturation



Stem cells have been characterized primarily by their marrow-repopulating potential, as outlined in Chapters 4. Early granulocytic progenitors form hematopoietic colonies in vitro and their more differentiated progeny express specific cell surface proteins that are critically important to myeloid differentiation and function. They mediate both the adhesion of precursors within the marrow and the vascular adhesion of mature neutrophils that is critical to normal neutrophil activation. Other proteins serve as receptors that recognize pathogens or as stimulatory peptides that facilitate activation of phagocytosis and killing of organisms. Appropriate expression of these surface proteins plays an important role in normal neutrophil function, and abnormalities of their expression are implicated in a wide range of diseases affecting the neutrophil compartment. For example, congenital abnormalities in the surface expression of integrin proteins are responsible for failure of neutrophil adhesion in leukocyte adhesion deficiency, and acquired abnormalities of expression of the same proteins are hypothesized to underlie the abnormal peripheral circulation of immature precursors in myeloproliferative disease.[2] These markers also serve to help distinguish among the stages of myeloid commitment and maturation.

The phenotype of the early hematopoietic stem cells is $CD34^+/CD33^-$, with absence of lineage-specific markers. The common myeloid progenitor, colony-forming unit granulocyte, erythrocyte, macrophage, megakaryocyte (CFU-GEMM), is characterized by the coexpression of CD33 and CD34. CD33 is expressed at high levels on committed myeloid progenitors and on early precursors of both the granulocytic and monocytic lineages. Expression of CD33 wanes with granulocytic maturation, and it is absent or nearly absent beyond the myelocyte stage. CD33 is a member of the sialic acid-binding immunoglobulin (Ig)-like lectins (siglecs), which generally mediate cell–cell interactions and cell signaling. The precise biologic function of CD33 remains unknown.

Characteristic granulocyte markers acquired as the early myeloid progenitor cells become committed to the neutrophil lineage include CD45RA, myeloperoxidase (MPO), and CD38, all of which are expressed on the myeloblast. Further differentiation beyond the myelocyte stage is associated with acquisition of increased expression of CD16, CD11b/CD18 (Mac-1), and leukocyte alkaline phosphatase (LAP), all of which are expressed at high levels in mature neutrophils.

Neutrophil Granules and Their Content Proteins

The acquisition of granules and their content proteins is a critical part of the developmental program of granulocytes.[3] Acquired at specific identifiable stages of neutrophil maturation, these

intracellular and secretory organelles contain many of the requisite enzymes that mediate the oxidative and nonoxidative killing functions of neutrophils (see Table 25-1).

Primary (azurophilic) granules are acquired at the promyelocyte stage and contain a wide array of proteins, including myeloperoxidase, defensins, cathepsins, and ELANE. Secondary granules are secretory granules acquired at the transition to the myelocyte stage. Neutrophil secondary granules contain lactoferrin, the vitamin B_{12}–binding protein transcobalamin I, and the MMPs (neutrophil collagenase and gelatinase), as well as NGAL. With the exception of gelatinase, which is also expressed by monocytes, expression of the secondary granule proteins is restricted to neutrophils. Secondary granules and the synthesis of their contents therefore constitute a definitive marker of commitment to terminal neutrophil maturation. Furthermore, characteristic secondary granules are acquired at the same stage by eosinophils and basophils. Tertiary granules, containing primarily gelatinase, are formed during later stages of neutrophil maturation. Secretory vesicles are formed by endocytosis and contain plasma proteins.[4]

On stimulation, the neutrophil first mobilizes secretory vesicles, which contribute their membrane proteins, including abundant integrin receptors, to the plasma membrane. They may thus increase cellular adhesion by upregulating surface integrin expression in response to selectin stimulation or inflammatory mediators. Primary granules fuse with the phagosome and contribute to bacterial killing. Secondary and tertiary granules have a complex function. They are secretory granules, releasing the matrix-modifying MMPs collagenase (MMP-8) and gelatinase (MMP-9) into the extracellular milieu, enhancing neutrophil penetration into sites of inflammation. The function of lactoferrin and transcobalamin I remains poorly defined, but they are hypothesized to contribute to the antimicrobial response by sequestering iron and cobalamin, respectively, away from infecting organisms. Secretion also results in the contribution of membrane proteins to the plasma membrane and is the source of the prominent upregulation of surface integrin receptor Mac-1 (CD11b/CD18) expression that occurs on neutrophil activation. Finally, they also fuse intracellularly with the phagosome to help promote bactericidal activity.

The fusion of azurophilic and peroxidase-negative granules allows for cross-exposure to their contents within the phagosome. These proteins are carefully sequestered in separate organelles, preventing premature activation and damage to the resting neutrophil; on fusion, the contents of the two granule subtypes cooperate in generating the antimicrobial response. Hydrogen peroxide, a byproduct of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase in the secondary granule, in combination with MPO from the primary granules, produces hypochlorous acid, a highly toxic microbicidal agent. Additionally, both neutrophil gelatinase (MMP-9) and neutrophil collagenase (MMP-8) (secondary granule proteins) are produced as zymogens and are converted to their active forms by the action of ELANE released from the primary granules.

Current evidence largely supports the hypothesis that the content of neutrophil granules is determined primarily by the timing of synthesis of their respective content proteins. Studies have demonstrated that each distinct granule population is generated not by a sophisticated protein sorting mechanism but rather by a highly regulated transcriptional process that results in sequential gene expression. For example, because myeloperoxidase and the other primary granule proteins are expressed between the promyelocyte and the myelocyte stages of neutrophil development, they are packaged into the primary granules. Secondary granule proteins such as lactoferrin, on the other hand, are expressed between the myelocyte and the metamyelocyte

*These granule constituents are conventionally assigned to the secondary granule, but their exact compartment remains controversial. Some may be located in the tertiary granule or possibly in one of the other, heterogeneous small-granule populations.

stages and are hence packaged into the secondary granules. Overexpression of the secondary granule protein NGAL in HL60 cells, a leukemic cell line that is arrested at the myeloblast stage of differentiation, resulted in its incorporation into primary granules, lending empirical support to the concept that gene expression and protein sorting into granules are coordinate events. This hypothesis may, however, be a somewhat oversimplified view of granule protein sorting because there is some overlap of expression between certain primary and secondary granule protein genes. Whereas secondary granule protein gene transcription appears to be coordinately regulated, the sequence of primary granule protein gene expression is much less synchronous. The defensins are expressed later than the other primary granule proteins, and defensin transcription appears to be regulated by the same transcriptional regulatory pathway as the secondary granule proteins gelatinase (MMP-9) and lactoferrin.[5] Indeed, the defensins are the only primary granule proteins that are absent in patients with neutrophil-specific granule deficiency (SGD). This suggests that the presence of defensin would be targeted to the secondary granule.[6] Consequently, how defensins are directed exclusively to the primary granule remains unclear.

CONTROL OF GRANULOPOIESIS

Granulocytes arise from pluripotent hematopoietic stem cells by a process of commitment, proliferation, and differentiation. Stem cells are long-lived cells capable of both self-renewal and differentiation to lineage-specific–committed progenitors. The process governing the cell fate decision that takes a stem cell down the path to lineage commitment and the subsequent factors that regulate lineage-specific differentiation have been the subjects of intense study for several decades. Three models of hematopoietic cell differentiation have been proposed to address the mechanism underlying lineage commitment and differentiation of the pluripotent stem cell. The first or inductive model proposes that lineage commitment and differentiation are the result of external stimuli (e.g., growth factors, stroma). A second model, the stochastic model, emphasizes intrinsic cellular factors as being critical to hematopoiesis; a third model combines the features of the first two. It appears likely that the transition from a stem cell to a committed progenitor is largely stochastic, although the subsequent maturation from progenitor to precursor cell to mature neutrophil requires cytokines. Controversy remains as to whether cytokines and the BM microenvironment play an instructive or a permissive role in influencing stem cell commitment and in inducing the proliferation and maturation of committed progenitors. As discussed subsequently, this complex issue has been elucidated in mice with homologous null mutations in specific cytokines and their cognate receptors, alone or in combination.

Cytokine Regulation of Myeloid Proliferation and Differentiation

Early progenitor cells express receptors for multiple cytokines, but expression becomes more restricted as the cell becomes committed to a specific lineage.[7] As a consequence of this broad range of cytokine receptor expression, early progenitors respond to combined growth factors, many of which show synergy of activity. The "early-acting" cytokines include the interleukins IL-1 and IL-6; stem cell factor (SCF); FLT3 ligand; and several others, including granulocyte colony-stimulating factor (G-CSF). IL-3 is important in directing the pluripotent stem cell toward the myelomonocytic lineage, giving rise to the mixed myeloid progenitor (CFU-GEMM). Subsequent stages leading to commitment- and lineage-restricted differentiation are governed by more "late-acting" cytokines (Fig. 25-2).

The major cytokines mediating neutrophil maturation are G-CSF and granulocyte macrophage colony-stimulating factor (GM-CSF). G-CSF not only supports the survival and proliferation of developing myeloid cells at all stages of differentiation but also increases the functional activity of mature neutrophils. Although the major role of G-CSF is thought to be the induction of neutrophil proliferation and differentiation, the G-CSF receptor (G-CSFR) is expressed on a wide range of cell types. In addition to myeloid progenitors and precursors at all stages of neutrophil differentiation, G-CSFR is expressed on platelets; monocytes; lymphocytes; and several nonhematopoietic cells, including endothelial cells and placenta. The role of G-CSF as both an early- and late-acting cytokine is underscored by the successful use of G-CSF to mobilize early progenitors into the peripheral blood for stem cell collection and to speed neutrophil recovery after chemotherapy.

The G-CSFR is a member of the cytokine receptor superfamily that signals through activation of the JAK–STAT (Janus kinase signal transducer and activator of transcription) pathway and the Ras pathway. Ligand binding induces homodimerization of the receptor, leading to a cascade of downstream phosphorylation events. Dimerization leads to phosphorylation of associated JAK kinases that in turn phosphorylate STAT1 and STAT3. In addition, the activated G-CSFR also phosphorylates mediators of the Ras–mitogen-activated protein (MAP) kinase pathway by tyrosine phosphorylation of Shc.[8]

The importance of G-CSF in myeloid proliferation and differentiation has been studied in G-CSF–null and G-CSFR–null mice. Mice lacking G-CSF or G-CSFR had markedly decreased myeloid

progenitors and impaired neutrophil production, with low circulating neutrophil counts. In addition, G-CSF–null mice had impaired neutrophil mobilization, and mature neutrophils from G-CSFR–null mice had increased susceptibility to apoptosis, supporting the role of the G-CSF pathway in sustaining the mobilization, survival, and function of mature neutrophils as well. However, despite all of these profound abnormalities, G-CSF/G-CSFR knock-out mice continue to make some neutrophils, suggesting that alternative overlapping cytokine pathways support granulocyte development.

GM-CSF also induces proliferation and differentiation of myeloid precursors. The GM-CSFR is a heterodimeric protein composed of an α- and a β-subunit. The α-subunit binds GM-CSF. The β-subunit is shared by the GM-CSFR and the receptors for IL-3, IL-5, and IL-6. The β-subunit does not bind ligand but is necessary for the high-affinity ligand binding to the αβ-heterodimer of each receptor. Signaling through the GM-CSFR also depends on the JAK–STAT pathway, signaling through JAK2, and serves to activate the Ras–MAP kinase pathway. Of interest, however, the GM-CSF–null mouse lacks any defect in hematopoiesis. Mice with null mutations in both G-CSF and GM-CSF had more profound neutropenia in the perinatal period but the same levels of neutrophils in adulthood as those mice solely lacking G-CSF only.

Transcriptional Regulation of Myeloid Differentiation

Lineage-specific maturation of committed hematopoietic progenitor cells is ultimately driven by transcription factors, which have been hypothesized to be the final common pathway leading to commitment and differentiation of the pluripotent stem cell.[9] The role of transcription factors in cellular proliferation, differentiation, and survival of stem cells during hematopoiesis in the mammalian BM has been well established. Studies of the regulation of individual genes that show tissue- and stage-specific myeloid expression have implicated a small number of transcription factors that are responsible for directing both phenotypical myeloid maturation and the expression of functionally important myeloid genes. As described in detail subsequently, this role is underscored by the observations in AML, in which disruption of differentiation and defective myeloid-specific gene expression are linked to pathognomonic chromosomal translocations that result in the dysregulation of transcription factor expression.

Maturation of multipotent progenitor stem cells into specialized blood cells (lymphocytes, erythrocytes, neutrophils, monocytes, and eosinophils, among others) is regulated by a well-orchestrated interplay of transcription factors that are capable of instructing the expression of a specific set of genes within a specific lineage. Gene knock-out technology and overexpression studies, in conjunction with newer techniques that involve the use of multicolor fluorescence-activated cell sorting (FACS), have aided in delineating several transcription factors critical to the development of specific hematopoietic lineages. On the basis of these studies, critical transcription factors have been classified into two major categories. The first category includes factors such as stem cell leukemia transcription factor (SCL), GATA2, and AML factor-1 (AML-1) now known as Runx1, that influence differentiation to all of the hematopoietic lineages; the second category comprises the master regulators of lineage development, including GATA1, PU.1, and CCAAT enhancer–binding protein-α (C/EBPα).

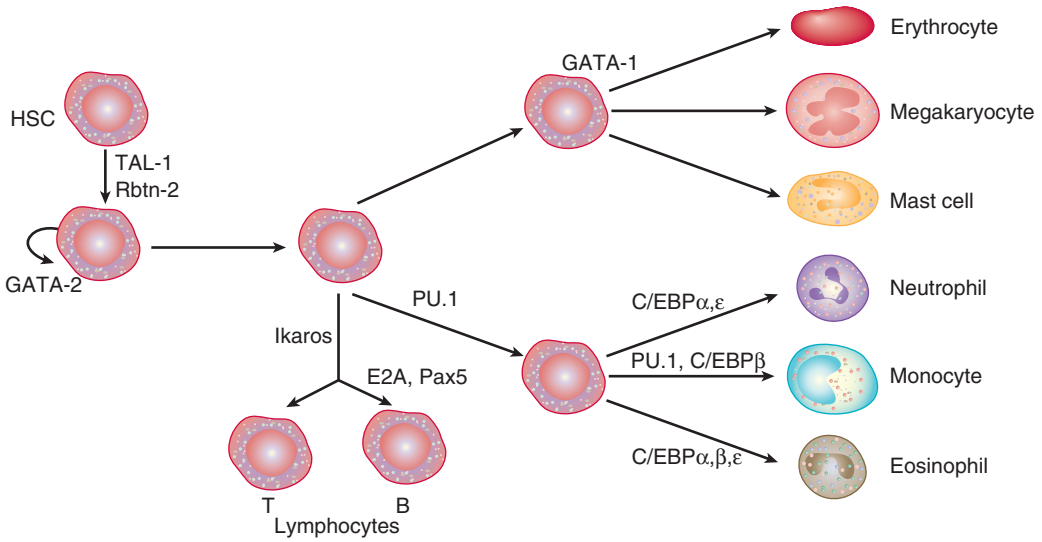

Figure 25-3 SIMPLIFIED SCHEMA OF TRANSCRIPTIONAL REGULATION OF HEMATOPOIESIS. *C/EBP,* CCAAT enhancer–binding protein; *HSC,* hematopoietic stem cell; *SCL,* stem cell leukemia transcription factor.

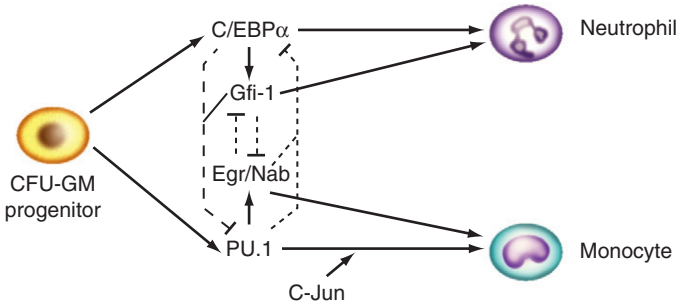

Figure 25-4 TRANSCRIPTION FACTOR CROSS-TALK AFFECTING NEUTROPHIL AND MONOCYTE DEVELOPMENT.

These factors not only promote lineage-specific gene expression but also suppress alternative lineage pathways. Fig. 25-3 summarizes the postulated role of several key transcription factors during hematopoietic development. Myeloid progenitors exhibit multilineage patterns of gene expression. Studies by Laslo et al[10] elegantly demonstrated that cell fate determination is dependent on subtle changes in expression levels of transcription factors, which regulate differential lineage maturation. For example, levels of PU.1 expression are increased by Egr-1/Nab-2 in developing macrophages; at the same time, Egr-1 represses the expression of the neutrophil specific Gfi-1 transcription factor, thereby simultaneously repressing the neutrophil development program (Fig. 25-4).

Transcription Factors Regulating Myeloid Differentiation and Myeloid-Specific Gene Expression

Runx1

Runx1 (AML-1) belongs to a family of highly conserved transcription factors that harbors a 128-amino-acid motif referred to as the *Runt domain*. The Runt domain functions in DNA binding, protein–protein interaction, and adenosine triphosphate binding and contributes to nuclear localization.[11] This family of transcription factors, also known as the core binding factor (CBF) family, has been implicated in specification of cell fate and has a role in myeloid differentiation and lineage-specific granulocytic function.

Runx1 is the DNA-binding α-subunit of the CBF complex. Together with CBFβ, a widely expressed protein that enhances the DNA-binding affinity of the α-subunit, Runx1 binds the consensus DNA motif 5′ Pu ACCPuCA 3′ as a dimer. Disruption of the Runx1 gene in mice results in embryonic lethality resulting from a failure of definitive hematopoiesis in the fetal liver. Although high levels of Runx1 expression have been reported in the early stages of myeloid differentiation, its expression levels decrease beyond the promyelocytic stage of differentiation. In concordance with its pattern of expression, Runx1 has been implicated in regulating a number of genes expressed early in the myeloid development pathway, including GM-CSF, macrophage colony-stimulating factor (M-CSF) receptor, myeloperoxidase, ELANE, and IL-3, among others. In addition to activating lineage-specific myeloid markers, Runx1 has been shown to stimulate the G1 to S transition in myeloid and lymphoid cell lines.

A significant percentage (10%-20%) of human leukemias have been found to be associated with mutations in the Runx1 gene. Most common of these is the t(8;21) translocation, which results in the Runx1-ETO (8, 21 oncoprotein) fusion protein. In Runx1-ETO, the Runt domain of Runx1 is fused in frame with the ETO transcriptional corepressor. The fusion protein has been hypothesized to function predominantly as a repressor that inhibits expression of genes that are normally activated by Runx1. For example, the tumor suppressor gene p14/p19(ARF), a critical Runx1 target gene that is necessary for the activation of p53 function, is normally activated by Runx1 but is repressed by Runx1-ETO. The mechanisms underlying Runx1 function through its target genes are not yet fully understood. Studies in sea urchins, however, have suggested that AML-1 regulates genes that contribute to chromatin architecture during cell proliferation. It has also been shown that Runx1 functions within a narrow window during development by assisting in the opening of chromatin associated with genes that are vital to hematopoietic development and for the formation of transcription factor complexes on these genes.[12]

Studies involving mouse knock-in models of Runx1-ETO expression have indicated that the fusion protein alone is not sufficient to cause leukemia. These animals are more susceptible to mutagen-induced AML, however, suggesting that Runx1-ETO is part of a multistep process that contributes to leukemogenesis. Although the fusion partner of Runx1 (e.g., ETO) may contribute to the role of the Runx1 fusion protein in leukemogenesis, the primary cause of the disease is thought to be the dysregulation of Runx1-specific target genes that are directly dependent on the Runt domain of Runx1.

CCAAT Enhancer–Binding Protein Family of Transcription Factors

CCAAT enhancer–binding proteins (C/EBPs) are a family of basic region-leucine zipper (b-ZIP) transcription factors that recognize the consensus DNA-binding sequence 5′TKN NGYAAK3′ (Y = C or T; K = T or G) within the regulatory regions of target genes. C/EBP family proteins have been shown to bind DNA as either homo- or heterodimers. This family of transcription factors, which plays a crucial role in hematopoiesis, includes C/EBPα,-β,-γ, -δ,-ε, and -ζ (CHOP-GADD 153), all of which contain highly homologous carboxyl-terminal (C-terminal) dimerization (leucine zipper) domains and DNA-binding (basic region) motifs but differ in their amino-terminal (N-terminal) transactivation domains, with the exception of CHOP-GADD 153, which lacks this domain altogether.[9] Of interest, CHOP-GADD 153 can dimerize with and inhibit transactivation by C/EBPα,-β, and -ε and is found at a breakpoint in liposarcomas resulting in the TLS-CHOP fusion protein.

With the exception of C/EBPε, which is expressed exclusively in the late stages of granulopoiesis and in T lymphocytes, the other C/EBP members are expressed in a wide variety of cells, including liver, adipose tissue, lung, intestine, adrenal gland, and peripheral blood mononuclear cells and placenta. Both C/EBPβ and C/EBPδ are expressed at high levels in late-stage granulocytes. The C/EBP family members are known to exert pleiotropic effects in the tissues in which they are expressed. This may be because of their tissue- and stage-specific expression, their ability to dimerize with members of their own family and of the Fos/Jun and ATF/CREB families of transcription factors, and their ability to interact with other transcription factors such as nuclear factor-κB (NF-κB) and specificity protein-1 (Sp-1).

The C/EBP factors have been implicated in regulating the differentiation of a variety of tissues. C/EBPα plays a role in adipocyte differentiation: Inhibition of C/EBPα blocks adipocyte differentiation, and overexpression of C/EBPα induces adipocyte differentiation. Regulation of constitutive hepatic genes as well as acute-phase response genes in the liver involves several C/EBP family members, particularly C/EBPα. Modulation of myelomonocytic differentiation is also attributed to the activity of C/EBP family members. The importance of this family of transcription factors in myeloid differentiation has been demonstrated by the study of hematopoietic abnormalities observed in mice with targeted disruption of C/EBPα, -β, and -ε.

C/EBPα

C/EBPα has been postulated to be a master regulator of the granulocytic developmental program. It is expressed at high levels throughout myeloid differentiation and has been shown to bind to the promoters of multiple myeloid-specific gene promoters regulating gene expression at many different stages of myeloid maturation. Although C/EBPα$^{-/-}$ mice die perinatally because of defects in gluconeogenesis that result in fatal hypoglycemia, they also have a selective early block in the differentiation of granulocytes without affecting either monocyte/macrophage maturation or the differentiation of other hematopoietic lineages. Myeloid cells from C/EBPα$^{-/-}$ mice lack the G-CSFR, and it has been postulated that lack of mature neutrophils in these mice may be caused by the lack of G-CSFR. However, the myeloid defect in C/EBPα$^{-/-}$ mice is more severe than that seen in G-CSFR$^{-/-}$ mice, suggesting that C/EBPα has additional functions vital to granulocytic maturation.

*C/EBP*α is a single exon gene, but it is expressed as two isoforms that arise from alternate translation start sites that give rise to a full-length C/EBPαp42 and a truncated dominant negative C/EBPαp30 isoform.[13] Translational control of C/EBPα isoform expression is orchestrated by a conserved upstream open reading frame (uORF) in the 5′ untranslated region (5′UTR). This region is thought to be responsive to the activities of the translation initiation factors eIF4E and eIF2[14] such that an increase of eIF2 or eIF4E activity results in an increase in expression of the shorter p30 isoform.[13]

Several groups have reported mutations in the C/EBPα gene in a subset of patients (~10%) with AML presenting with a normal karyotype.[15] These mutations can be broadly classified into two main categories. The first includes in-frame mutations clustered in the highly conserved C-terminus of the C/EBPα protein. The second category involves frame-shift mutations at the N-terminus of C/EBPα, resulting in the premature termination of the full length C/EBPαp42 isoform while keeping the truncated C/EBPα p30 protein intact.[16] The remaining C/EBPαp42 is thought to be rendered inactive by the dominant-negative activity of the p30 isoform by an unknown mechanism. Additionally, a recent study has shown that mice homozygously expressing p30 C/EBPα from the *C/EBP*α locus develop AML with complete penetrance.[17] Thus, changes in the expression ratio of the two C/EBPα isoforms play a role in cell fate.[15,18]

The expression of C/EBPα is associated with growth arrest and differentiation of granulocyte precursor cells. This block in proliferation is thought to occur via the interaction of C/EBPα with the cyclin-dependent protein kinases cdk2 and cdk4, resulting in a block in cell proliferation by inhibiting these cell cycle kinases. In addition, C/EBPα inhibits E2F-dependent transcription, which in turn contributes to inhibition of cell proliferation and induction of differentiation associated with C/EBPα-induced granulopoiesis.

C/EBPβ

Expression of C/EBPβ increases during myeloid maturation and has been shown to be important for monocyte/macrophage gene expression and development. Mice lacking the C/EBPβ gene demonstrate decreased B-cell levels and defects in macrophage activation and function and are more prone to microbial infections. The C/EBPβ knock-out studies reveal that this transcription factor is not essential for myeloid development per se, but knock-in of C/EBPβ into the C/EBPα locus of C/EBPα$^{-/-}$ mice rescues granulopoiesis. Several monocyte/macrophage-specific genes are activated by C/EBPβ, including the G-CSF receptor, lysozyme, CD11c, monocyte chemoattractant protein-1 (MCP-1), IL-6, IL-8, and nitric oxide synthase, among others. Similar to C/EBPα, multiple isoforms of C/EBPβ are generated from a single transcript through the use of three translation initiation sites and a leaky ribosome scanning mechanism. The shortest of these isoforms, initiated at the most 3′ AUG, results in the formation of liver-enriched inhibitory protein (LIP), which lacks the N-terminal activation domain present in full-length C/EBPβ and has been implicated as a negative regulator of C/EBPβ function. It has been suggested that the ratio of C/EBPβ to LIP may affect cellular proliferation and differentiation. The activity of C/EBPβ is regulated posttranscriptionally through protein–protein interactions and covalent modifications. For example, in early myeloid progenitor cells, C/EBPβ is found in an unphosphorylated state in the cytoplasm. However, on differentiation, C/EBPβ becomes phosphorylated and translocates to the nucleus.[19]

C/EBPγ

C/EBPγ is a ubiquitously expressed C/EBP family member that was first identified by its affinity for *cis*-regulatory sites in the Ig heavy chain promoter and enhancer. C/EBPγ contains a C/EBP-like b-Zip domain but lacks an N-terminal transactivation domain and can inhibit transcriptional activation of other C/EBP members in some cell types. Impairment of natural killer cytotoxic activity and of interferon-γ production has been reported in C/EBPγ$^{-/-}$ mice.

C/EBPδ

C/EBPδ is expressed at low or undetectable levels in several tissues of adult mice and humans. Expression has been shown to dramatically increase on induction with bacterial lipopolysaccharide (LPS) and inflammatory cytokines, suggesting a role for C/EBPδ in acute-phase and inflammatory response. Double-knock-out experiments using C/EBPβ and C/EBPδ suggest a synergistic role for these two

C/EBP family members in controlling terminal adipocyte differentiation. Of interest, both C/EBPβ and C/EBPδ are expressed during late neutrophil development and have been postulated to play roles in late neutrophil gene expression.

C/EBPε

CCAAT enhancer-binding protein ε (C/EBPε) is the most recently described C/EBP protein. The human C/EBPε gene resides on chromosome 14 and is transcribed by two alternative promoters, Pα (thought to function in mature neutrophils) and Pβ (thought to function in BM). A combination of differential splicing and alternate promoter usage results in four messenger RNA (mRNA) isoforms 2.6 kilobases and 1.3 to 1.5 kilobases in size, from which three proteins of 32.2 kd, 27.8 kd, and 14.3 kd have been described. C/EBPε$^{-/-}$ mice produce hyposegmented granulocytes that are functionally defective. Late in life, these mice develop myelodysplasia. Absence of C/EBPε is thought to block the later steps in terminal differentiation of mature segmented granulocytes. Mutant mice usually survive 2 to 5 months and eventually succumb to low-pathogenicity bacterial infections. C/EBPε thus plays a crucial role in terminal granulocytic differentiation.

C/EBPε$^{-/-}$ mice have wild-type levels of the G-CSF receptor, and the defects manifested in these mice are confined to late-stage gene expression associated with the function of the mature neutrophil. Recently, it has been demonstrated that the ability of G-CSF to regulate myeloid differentiation is dependent on the induction of C/EBPε. The mRNA of several genes, including p47 phox (a component of the neutrophil NADPH oxidase complex), as well as the secondary granule protein (SGP) genes, are either absent or abnormal in the BM of C/EBPε$^{-/-}$ mice. C/EBPε is suggested to play a critical role in the regulation of host antimicrobial defense.

Neutrophils from C/EBPε$^{-/-}$ mice have morphologic and biochemical features very similar to those observed in patients with neutrophil-specific SGD. SGD is an extremely rare congenital disorder that is characterized by frequent and severe bacterial infections. Patients with SGD have defects in neutrophil function, including atypical nuclear morphology, impaired bactericidal activity, and abnormalities in neutrophil migration; they also lack both neutrophil and eosinophil secondary granule proteins. Recent sequence analyses of genomic DNA from two patients with SGD revealed mutations within the C/EBPε gene, resulting in a mutant protein lacking the dimerization and DNA-binding domains and hence transcriptional activity. Lack of functional C/EBPε activity has been postulated to underlie the observed pathology in these patients.

C/EBPζ

C/EBPζ-C/EBP homologous protein (CHOP) is a C/EBP family member that was originally isolated as the product of a gene induced in response to DNA-damaging agents. It has subsequently been shown to be induced by various extracellular or endoplasmic reticulum stresses. The basic region of CHOP is less well conserved than that of the other C/EBP family members, and CHOP does not seem to bind to canonical C/EBP *cis* elements. CHOP has been shown to interfere with the transcriptional activity of C/EBPβ in a manner dependent on its leucine zipper.

PU.1

PU.1 is a member of the Ets family of transcription factors and is expressed abundantly in B cells and macrophages. Expression of PU.1 has also been reported in granulocytes and eosinophils as well as in CD34^{+} hematopoietic progenitor cells. Whereas high levels of PU.1 expression in fetal livers of mice preferentially direct macrophage development, low levels of PU.1 result in B-cell development. C-Jun, another member of the b-Zip family of transcription factors, serves as a coactivator of PU.1 during macrophage development. It has been demonstrated that overexpression of c-Jun in myeloid progenitor cells results in macrophage development. Recent studies have revealed that downregulation of c-Jun by C/EBPα is necessary for granulocytic maturation and appears to be the mechanism through which C/EBPα blocks macrophage development. C/EBPα not only binds to the promoter of the c-*jun* gene and decreases its expression but also binds PU.1, thereby inhibiting its activity.

PU.1-binding sites have been reported in almost all myeloid-specific promoters reported to date, including those for M-CSF, GM-CSF, and G-CSF receptors, all of which play critical roles in myeloid cell development. PU.1 activity is modulated both by covalent modifications and by protein–protein interactions. For example, phosphorylation of PU.1 by casein kinase II or by JNK kinase leads to increased transcriptional activity.

Abrogation of PU.1 expression in PU.1$^{-/-}$ mice results in perinatal lethality accompanied by the absence of mature monocytes/macrophages and B cells and delayed and reduced granulopoiesis. After in vitro differentiation, embryonic stem cells derived from PU.1$^{-/-}$ blastocysts fail to express mature myeloid cell markers, suggesting that PU.1 is not essential for the initial events associated with myeloid lineage commitment but is necessary for the later stages of development.

Growth Factor Independence-1

The growth factor independence-1 (Gfi-1) gene was first identified as a target of proviral insertion after infection with Moloney murine leukemia virus (MoMuLV) resulting in interleukin-2 factor independence of a rat lymphoma cell line.[20] Gfi-1 is a highly conserved gene that encodes a 55kD nuclear proto-oncogene that harbors six C_2H_2 type zinc finger domains at the carboxy terminus and a 20–amino acid stretch at the N-terminus known as the SNAG domain.[20] The SNAG domain, which appears to be conserved in the Snail/Slug family of proteins, has been shown to confer transcriptional repressor activity on Gfi-1. The human Gfi-1 gene is located on chromosome 1p22, and its closely related paralog Gfi1b maps to chromosome 9q34. Whereas Gfi-1 is expressed at high levels in the thymus and BM, Gfi1B expression is confined to the BM and spleen. Homozygous knockout of Gfi-1B results in embryonic lethality at day E15 even though myelopoiesis is normal. Death in these mice has been attributed to a failure of erythropoiesis and megakaryopoiesis.

The essential role of Gfi1 in neutrophil differentiation became apparent after two reports of gene disruption in mice. Gfi1-null mice are severely neutropenic and eventually succumb to bacterial infections. In addition, these mice lack mature neutrophils, and their granulocyte precursors are unable to differentiate into mature neutrophils upon induction with G-CSF. These cells also lacked SGP expression reminiscent of C/EBPε$^{-/-}$ granulocytes. Gfi-1$^{-/-}$ BM contained an atypical Gr1^{+}Mac1^{+} myeloid precursor cell that appears to share characteristics of both granulocyte and macrophage precursors. Ectopic expression of Gfi1 in ex vivo sorted Gfi1$^{-/-}$ progenitor cells restored G-CSF–mediated neutrophil maturation to these cells. These observations provide evidence for the critical role of Gfi1 in the neutrophil maturation program. Recent studies have further demonstrated that Gfi-1 together with C/EBPε synergize to transactivate the promoters of late myeloid genes. This synergy is lost in a patient with SGD, who has a heterozygous substitution mutation in the C/EBPε gene and decreased levels of Gfi-1 in the BM.

Recently, heterozygous dominant negative mutations in the Gfi1 gene have been described in two patients with severe congenital neutropenia (SCN), underscoring the role of Gfi1 in the neutrophil maturation pathway. It has been suggested that mutant Gfi1 in these patients alters the expression of ELANE mutations that are commonly associated with SCN (see below). This observation confirms the vital role Gfi1 plays in human granulopoiesis.

CCAAT Displacement Protein

CCAAT displacement protein/cut (CDP) is a ubiquitously expressed, highly conserved, homeodomain (HD) protein with extensive homology to the *Drosophila* cut protein. CDP has been shown to act as a

repressor of developmentally regulated genes, including the phagocyte-specific cytochrome heavy chain gene (gp91 phox), which is expressed exclusively in differentiating granulocytes.[21] Overexpression of CDP in 32Dcl3 myeloid cells blocks G-CSF–induced expression of SGP genes without blocking phenotypical maturation. CDP therefore acts as a negative regulator of stage-specific expression of both early and late neutrophil-specific genes.

The CDP homeobox protein contains three highly conserved DNA-binding repeats referred to as *cut repeats* (CR1, CR2, CR3) and a HD, each of which is capable of recognizing and binding specific DNA motifs in target genes. This may explain why the CDP molecule as a whole does not have a well-defined consensus DNA-binding sequence. The cut repeats cannot bind DNA as monomers but in combination exhibit high DNA-binding affinity. It has further been suggested that CDP-binding activity is restricted to proliferating cells, in which CDP target genes are repressed. These targets are upregulated as cells undergo cell cycle arrest and terminal differentiation in association with a decrease in CDP binding. Target genes of CDP include c-myc, c-mos, and the thymidine kinase (TK), cdk inhibitor p21(WAF1/CIP1), cystic fibrosis transmembrane conductance regulator (CFTR), transforming growth factor-β (TGF-β) type II receptor, gp91 phox, major histocompatibility complex (MHC) class I locus, and neutrophil SGP genes.

During myeloid differentiation, CDP binding has been shown to regulate genes that are expressed at widely disparate stages of differentiation. For example, it represses the gp91 phox gene, which is expressed at a much earlier time in myelopoiesis than is the case for the lactoferrin gene. The mechanism by which CDP mediates repression and the means by which it modulates stage-specific gene expression at different stages of differentiation within a single lineage are not fully understood. CDP is reported to have repressive activity associated with its ability to be displaced by a positive transacting factor involving the CR1 and CR2 cut repeats. However, other modes of repressive activity involving the two active repression domains within the C terminus of CDP also have been reported. CDP has been shown to function as a repressor of transcription via chromatin modification through recruitment of histone deacetylases (HDACs), consistent with the notion that transcriptional silencing is associated with hypoacetylated histones. Both acetylation and phosphorylation of CDP are posttranscriptional modifications that have been postulated to regulate CDP function. Thus, differential modification, by phosphorylation or acetylation, of CDP-DNA complexes binding the promoters of target genes could result in the observed differential repression exerted by CDP during neutrophil development.

ROLE OF DEVELOPMENTALLY IMPORTANT NEUTROPHIL-SPECIFIC GENES IN DISEASE

Our understanding of the role of neutrophil-specific genes has been enhanced by the study of mice in which targeted disruption of a gene results in phenotypically important defects in neutrophil differentiation and function. Similarly, the importance of these genes has been underscored by the analysis of naturally occurring genetic events within these genes that result in human disease. The links between some genes and the diseases induced by their dysfunction may be anticipated by their important roles in neutrophil differentiation and function, but the pathophysiologic links between others and the diseases they induce remain elusive (Table 25-2).

Disruption of neutrophil transcriptional regulation is a recurring theme in the pathogenesis of leukemia. Nearly half of patients with AML have pathognomonic translocations resulting in the fusion of a transcription factor with a tissue-specific gene. These translocations have been shown to interfere with myeloid differentiation and emphasize the role of transcription factors in that process.

As discussed previously, the same transcription factors that are implicated in the induction of neutrophil differentiation also direct the expression of genes encoding neutrophil-specific functional proteins. The link between morphologic differentiation and synthesis of neutrophil functional proteins is illustrated by the demonstration that

Table 25-2 Differentiation-Specific Genes Implicated in Neutrophil Disorders

TRANSCRIPTION FACTORS
C/EBPα, PU.1, RARα, AML1, and others in AML
C/EBPε and Gfi-1 in specific granule deficiency
Gfi-1 in neutropenia
GRANULE AND FUNCTIONAL PROTEINS
Neutrophil elastase in Kostmann syndrome and cyclic hematopoiesis
gp91 phox in chronic granulomatous disease
ADHESION MOLECULES, RECEPTORS
Common β-chain of integrin receptors in LAD
G-CSF receptor mutations in AML arising in patients with Kostmann syndrome

AML, Acute myeloid leukemia; *C/EBP,* CCAAT enhancer–binding protein; *G-CSF,* granulocyte colony-stimulating factor; *gp91 phox,* glycoprotein 91 phagocyte nicotinamide adenine dinucleotide phosphate oxidase; *LAD,* leukocyte adhesion deficiency.

disruption of C/EBPε signaling results in SGD associated with both morphologic abnormalities and increased infections attributable to neutrophil functional defects. It is intriguing that C/EBPε$^{-/-}$ mice share these abnormalities while also demonstrating a predilection for the development of myelodysplasia (i.e., myelodysplastic syndrome [MDS]). Although the development of MDS or AML has not been reported in patients with SGD, the deficiency is a rare disease described in less than a dozen patients, so a tendency to develop MDS or AML might be difficult to document.

Other diseases have been linked to defects in functionally important neutrophil proteins. Abnormalities in integrin expression, notably, loss of the common β-chain of the integrin receptors, result in leukocyte adhesion deficiency, and absence of any of the components of the reduced NADPH oxidase leads to chronic granulomatous disease.

Abnormalities in granule protein gene expression again underscore the complexity of the granulocyte functional program. Congenital absence of many individual granule proteins, including myeloperoxidase, lactoferrin, and transcobalamin, has been described. In the absence of the more global defects seen in SGD, which presumably reflect more complex abnormalities than simple protein deficiency, these defects tend to be incidental laboratory findings with minimal or no associated pathology.

One prominent exception to that observation is the association between point mutations in the gene encoding NE (ELA2; neutrophil elastase, ELANE) and SCN, or Kostmann syndrome. The pathogenesis of SCN originally was sought in studies of G-CSFR, supported by the observation of a truncation mutation in G-CSFR in select patients with Kostmann syndrome.[22] It was later demonstrated that these were acquired mutations that may predispose the patient to secondary AML but did not constitute the pathologic basis for the neutropenia itself. Subsequent studies have implicated ELANE in the pathogenesis of SCN. ELANE is a primary granule protein that digests elastin and has been implicated in the pathogenesis of emphysema. Linkage studies have linked heterozygous abnormalities in the NE gene to both SCN (Kostmann syndrome) and cyclic hematopoiesis. The link between elastase and the control of neutrophil cell mass remains a mystery.

Role of microRNAs in Controlling Gene Expression in Granulopoiesis

MicroRNAs (miRNAs) are 18 to 24 nucleotides long, noncoding RNAs that regulate eukaryotic gene expression in general by binding to specific sites in the 3′UTR of target genes and altering expression by destabilizing mRNA or blocking mRNA translation. miRNAs are

encoded in the genome and are initially transcribed by RNA polymerase II as long primary transcripts referred to as primary miRNAs (pri-miRNAs). These transcripts are recognized and processed by a ribonuclease called Drosha into 60 to 80 nucleotide intermediates called *precursor miRNAs* (pre-miRNAs), which are then exported to the cytoplasm, where a second ribonuclease termed *Dicer* cleaves pre-miRNAs to generate double-stranded 18- to 24–nucleotide-long miRNAs. The miRNAs are then incorporated into the RNA-induced silencing complex (RISC), a large protein complex that also contains the Argonaute or mRNA cleaving proteins. The miRNA guides the RISC complex to target complementary regions in the 3′UTRs of mRNAs, leading to repression of translation or destabilization of the mRNA by deadenylation.[23]

An increasing body of evidence implicates miRNA activity in mediating both normal and abnormal myelopoiesis.[24] MiRNAs have been shown to activate or be activated by myeloid-specific transcription factors such as C/EBPα and Gfi-1. For example, mir-223 is thought to be a direct target of C/EBPα, and its expression increases during granulopoiesis. Ablating mir-223 in mice results in the expansion of granulocyte precursor cells resulting from a cell autonomous increase in the number of granulocytic progenitors.[25] Additionally, overexpression of mir-223 in acute promyelocytic leukemia cells results in an enhanced capacity for granulocytic differentiation.[26] Mir-223 is thus thought to be a positive regulator of granulopoietic differentiation. Additionally, it has been shown that mir-223 targets E2F1, a master cell cycle regulator, by inhibiting translation of its mRNA. Thus, granulopoiesis appears to be regulated by a C/EBPα–miR-223–E2F1 axis, wherein miR-223 functions as a key regulator of myeloid cell proliferation associated with E2F1 in a mutual negative feedback loop.[27]

Eiring et al[28] have demonstrated another role for miRNAs in granulopoiesis. They demonstrated that mir-328 is downregulated in CML patients in blast crisis. Restoration of mir-328 expression restores differentiation by interaction with both the C/EBPα translational inhibitor hnRNP-E2 and the mRNA for PIM1, a survival factor. The interaction with hnRNP-E2 leads to the release of C/EBPα mRNA from hnRNA-E2–mediated translational inhibition through an interaction that is independent of its seed sequence. Thus, mir-328 appears to control cell fate by its ability to base pair with the 3′UTR of target mRNAs (PIM1) as well as by acting as a decoy for hnRNP binding, thus interfering with cell fate by releasing C/EBPα from translational inhibition.[28]

A role for mir-27 in granulopoiesis has also been documented. This miR targets the myeloid transcription factor Runx1, whose expression decreases during granulocytic differentiation in a mir-27–dependent manner. Anti-mir-27 treatment of immature myeloid progenitors resulted in an increase in the expression of Runx1 and impaired granulocytic differentiation.[29] In a separate study, the transcription factor Gfi-1 was shown to bind to the promoter of miR-196b and repress its expression, thereby promoting granulocytic maturation while repressing monocytic lineage development. Overexpression of miR-196b blocked granulopoiesis in granulocyte monocyte precursor cells.[30]

Thus, a growing number of feedforward and feedback regulatory loops involving specific miRNAs and myeloid-specific transcription factors that determine lineage development and fate have been recognized in recent years, thereby underscoring a vital role of miRNAs in granulopoiesis.

EOSINOPHIL PRODUCTION

Eosinophil precursors constitute approximately 3% of marrow progenitors, of which about two-thirds are myelocyte precursors and the remainder mature eosinophils (Fig. 25-5). Eosinophilic myelocytes are large cells with a single-lobed nucleus. The characteristic specific granules of eosinophils contain major basic protein, eosinophil cationic protein, eosinophil peroxidase, and eosinophil-derived neurotoxin. Eosinophils also contain primary granules that contain Charcot-Leyden crystal protein. Mature eosinophils are released from the marrow, where they circulate up to 18 hours before migrating to the tissues.

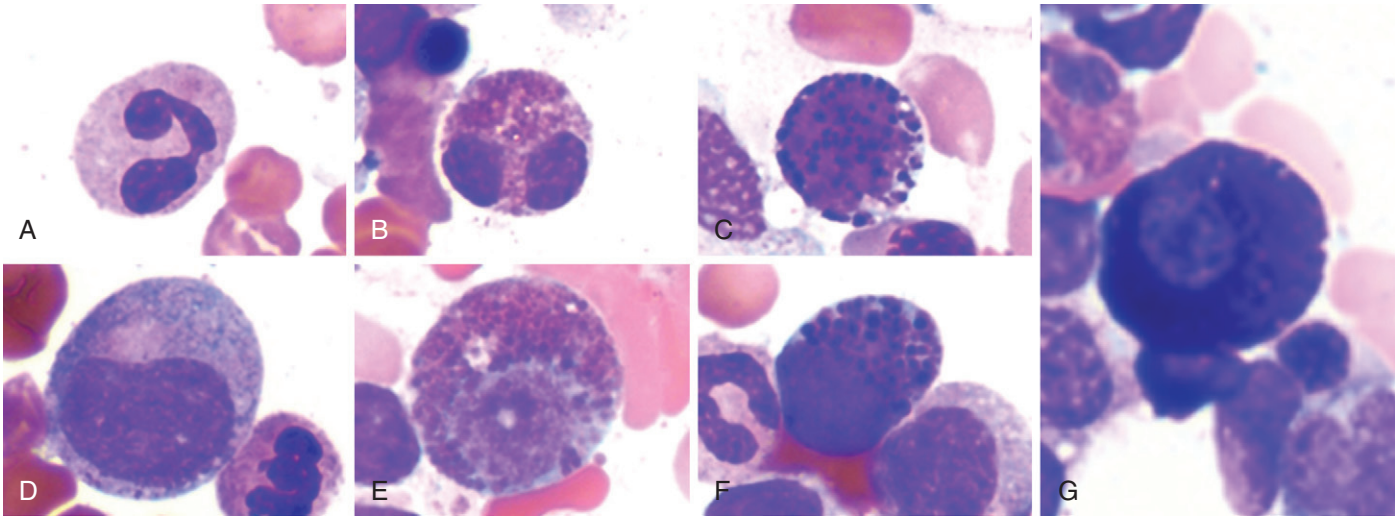

Figure 25-5 NEUTROPHILIC, EOSINOPHILIC, AND BASOPHILIC GRANULOCYTES; THEIR MYELOCYTE PRECURSORS; AND MAST CELLS. Eosinophilic and basophilic granulocytes are always best viewed compared with neutrophilic granulocytes because staining can vary from laboratory to laboratory and even from case to case. When compared with a neutrophil **(A),** the eosinophil **(B)** has larger and more red/orange-colored and almost refractile granules than the pink and barely perceivable granules in the neutrophil. Mature eosinophils are also frequently bilobed, but neutrophils tend to have three or four lobes. The basophil **(C)** has dense, dark blue granules that frequently overly the condensed and lobulated nucleus. The granules frequently obstruct the nucleus and are a much larger than the primary granules of promyelocytes. The myelocyte stage of maturation is when the secondary granules first appear **(D** to **F).** In the neutrophilic myelocyte **(D),** the secondary granules first appear in the Golgi region and have been describes as resembling the sunrise over the horizon, the "dawn of neutrophilia." The eosinophilic and basophilic myelocytes **(E** and **F)** are relatively infrequent in the bone marrow and are usually enumerated together with the mature forms. Mast cells **(G)** must be distinguished from basophils and basophilic myelocyte. Mast cells are larger and have quite numerous granules mostly in the cytoplasm. Mast cells have round nuclei, which are frequently obscured by the granules. A toluidine blue cytochemical reaction will be positive (metachromatic) in the granules of both basophils and mast cells. However, a mast cell tryptase immunostain used on a tissue section will be positive only in mast cells.

Eosinophils proliferate and mature under the influence of IL-3, IL-5, and GM-CSF. Evidence suggests that these cytokines are secreted by T cells as the stimulus to eosinophil production in many disorders associated with eosinophilia. Studies of idiopathic hypereosinophilic syndrome have described activating mutations in the platelet-derived growth factor receptor-α (PDGFR-α) that result in constitutive tyrosine kinase activation and eosinophil proliferation.

Transcriptional regulation of eosinophilic differentiation is mediated through PU.1 C/EBPα and -β. Because these same factors serve to induce myeloid differentiation, the modulation of the signals determining the choice between these two lineages is not well defined. It has been proposed that levels of GATA1 may be important in determining whether C/EBP expression induces the eosinophilic or the myeloid maturation program (see Chapter 70).

BASOPHIL AND MAST CELL PRODUCTION

Basophils and mast cells mediate allergic responses, where they are the central cells involved in IgE-induced immune responses to parasites and other allergens. Both cell types are derived from marrow precursors, but they have a very different ontogeny (see Fig. 25-5 and Chapter 71).

Basophils have a bilobed nucleus and characteristic intensely staining purple granules that may cover the nucleus. These granules contain glycosaminoglycans, predominantly heparin. Basophils differentiate from marrow progenitors and are released from the marrow as mature cells, where they circulate briefly, with a lifespan similar to that of neutrophils. Maturation occurs in response to IL-3, which serves both to induce basophilic differentiation and to mediate activation of mature basophils. Although IL-3 is the primary mediator of basophil development, studies of IL-3–null mice have demonstrated that it is not required for baseline production of basophils. It is, however, required for the induction of basophilia in response to parasitic infection. Other cytokines that influence basophil proliferation include GM-CSF, IL-5, and SCF.

Mast cells arise from marrow precursors but are released into the circulation as immature cells. They circulate only briefly in the peripheral blood before migrating to the tissues, where they complete their maturation. There remains some question about whether mast cells and basophils arise from a common precursor. In vitro studies showed that adding SCF and IL-3 to cultured $CD34^+$ cells results in an increased proliferation and maturation of both basophils and mast cells but did not establish a common progenitor cell for the two lineages. It is clear that SCF is especially effective in inducing mast cell proliferation; in fact, activating mutations in c-Kit, the SCF receptor, is the underlying molecular defect in cases of systemic mastocytosis.

MONOCYTOPOIESIS

Monocyte Ontogeny

Stages of Monocyte Differentiation

Monocytes originate in the BM from promonocytes, which constitute approximately 3% of the total cells in the normal marrow (Fig. 25-6). Promonocytes have round nuclei and basophilic cytoplasm. Differentiation occurs rapidly, with a maturation time of 50 to 60 hours, associated with two rounds of replication and morphologic maturation marked by progressive lobulation of the nucleus. Stress-induced release of monocytes occurs primarily through their premature release from the proliferating pool. Survival in the blood is short, approximately 8 to 72 hours. Monocytes then enter the tissues, where they develop into macrophages that may survive 2 to 3 months. Tissue-fixed macrophages are found in the lung (alveolar macrophages), the liver (Kupffer cells), the spleen, and the central nervous system (glial cells).

Monocytes also may serve as precursors to a subset of dendritic cells. Dendritic cells are professional antigen-presenting cells that arise from both myeloid and lymphoid precursor cells. The myeloid subset of dendritic cells arises from a precursor that can alternatively differentiate into macrophages. Similar cells have been generated for immunotherapy by exposing peripheral blood monocytes to GM-CSF and IL-4 in vitro.

Markers of Monocyte Maturation

Unique surface markers of monocyte maturation have been difficult to identify. In mice, the marker F4/80 was identified as a nearly universal marker of monocytes and macrophages; this antigen has been shown to be homologous to the human epidermal growth factor module containing mucin-like hormone receptor 1. The function of this receptor is unknown because knock-out mice have no phenotype.

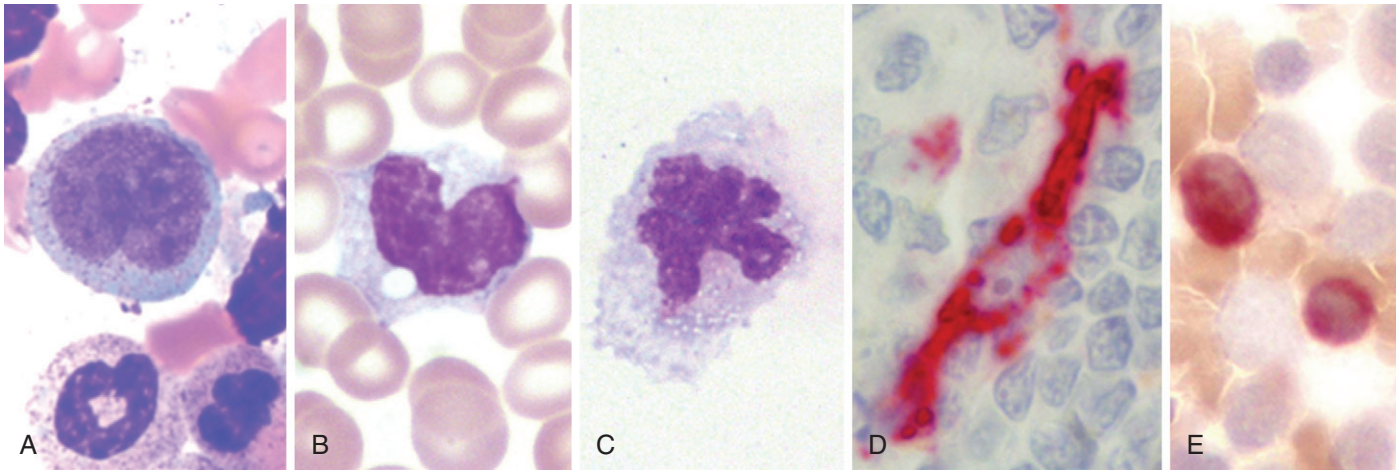

Figure 25-6 A PROMONOCYTE, MONOCYTE, MACROPHAGE, AND HISTIOCYTE. Promonocytes are rare in the bone marrow (BM) **(A)** and are more frequently seen during recovery or during marrow regeneration after chemotherapy or other insult. They are typically slightly folded and have nucleoli. The cytoplasm is moderately abundant and blue/grey with very faint granules. Monocytes seen in the blood **(B)** typically have more folded or horseshoe-shaped nuclei and more abundant grey cytoplasm frequently with vacuoles and rare granules. The macrophage **(C)** is seen in body fluid specimens such as peritoneal fluid or cerebrospinal fluid and resembles the blood monocyte. Tissue histiocytes are fixed in the tissues and are seen on tissue sections. The histocyte illustrated **(D)** is stained with CD68 and is from a lymph node. It likely represents a dendritic cell in a germinal center. Monocytes in the BM can be more easily enumerated with a nonspecific esterase cytochemical reaction such as alpha-naphthyl acetate esterase, which gives an orange/brown reaction product **(E).**

Monocyte precursor cells express the M-CSF receptor, lysozyme, the Fcγ receptor (II/III), and the scavenger receptor. Mature monocytes, similar to neutrophils, show high-level expression of CD11b/CD18. After differentiation to macrophages, the cells acquire expression of macrosialin (CD68), a glycoprotein of unknown function that may play a role in lipoprotein metabolism. Macrophages also express sialoadhesin, a member of the sialic acid–binding receptor family. Although its precise function has not been proved, sialoadhesin mediates binding to sialic acid moieties on cell surfaces and probably plays a role in macrophage cell–cell interactions and cell–extracellular matrix interactions.

CD14 is a major functional surface protein of the monocyte/macrophage lineage. CD14 is the receptor for LPS, leading to monocyte/macrophage activation. More recent studies have suggested that CD14 also may have a role in apoptosis.

Monocytes contain both primary (peroxidase-positive) and secondary (peroxidase-negative) granules. The primary granules of monocytes, similar to those of neutrophils, contain myeloperoxidase. Secondary granule fusion with the membrane on stimulation of monocytes results in upregulation of Mac1 and p150 and is thought to play a role in adhesion and diapedesis of stimulated monocytes.

Control of Monocytopoiesis

Cytokine Regulation of Monocyte Proliferation and Differentiation

The effects of colony-stimulating factor 1 (CSF-1 also known as M-CSF), the primary regulator of mononuclear phagocyte production, are thought to be mediated by the high-affinity receptor tyrosine kinase CSF-1 receptor (CSF-1R), encoded by the c-fms proto-oncogene. A total of five human or mouse mRNAs result from alternative splicing, and the alternative use of the 3′ untranslated region results in three isoforms of the CSF-1 protein, a secreted proteoglycan, a secreted glycoprotein, and a membrane-spanning cell surface proteoglycan.

The phenotypes of Csf1-null mice and of mice harboring an inactivating mutation in the coding region of CSF-1 (Csfop/Csf1op) (osteopetrotic mice) are virtually identical; features include toothlessness, low body weight, low growth rate, and deficient tissue macrophages. Additionally, the mutant mice have defects in both male and female fertility. Compared with their wild-type littermates, splenic erythroid burst-forming unit and high-proliferative-potential colony-forming cell levels in both Csf1op/Csf1op and $Csf1^{-}/Csf1^{-}$ mice were significantly elevated, consistent with a negative regulatory role for CSF-1 on erythropoiesis and on the maintenance and proliferation of primitive hematopoietic progenitors. The circulating CSF-1 concentration in CSF receptor-null ($Csf1R^{-}/Csf1R^{-}$) mice was elevated 20-fold, in agreement with clearance of circulating CSF-1 by CSF-1R–mediated endocytosis. Despite their overall similarity, several phenotypical characteristics of the $Csf1R^{-}/Csf1R^{-}$ mice were more severe than those of the Csf1op/Csf1op mice. The results indicate that all of the effects of CSF-1 are mediated via the CSF-1R but that additional effects of the CSF-1R could result from its CSF-1-independent activation.

Signaling through the CSF-1R appears to be critical for monocyte/macrophage development. Although little is known about the events that lead to stimulation of a monocyte/macrophage specific array of genes, it is clear that several transcription factors, probably stimulated by M-CSF–related signaling events, play vital roles in the development of this lineage. It should be noted, however, that the ability of phorbol esters to induce monocytic differentiation of myeloid cell lines through activation of the protein kinases Cα and Cδ suggests a role for the protein kinase C pathway in monopoiesis.

IL-3, G-CSF, and tumor necrosis factor all have been shown to synergize with M-CSF in the proliferation of macrophages. G-CSF also has been shown to induce the increased release of monocytes; this is an indirect effect dependent on the presence of M-CSF. Monocytes also have been demonstrated to have functional G-CSF receptors, although G-CSF appears to function mainly to decrease monokine secretion rather than to increase monocyte proliferation.

Transcriptional Regulation of Monocyte Differentiation

Of the several transcription factors that regulate the development of the monocyte/macrophage lineage, the most well-established is PU.1 because abrogation of PU.1 expression in $PU.1^{-/-}$ mice results in perinatal lethality accompanied by the absence of mature monocytes/macrophages and B cells and delayed and reduced granulopoiesis. A number of factors, the most notable of which is c-Jun, cooperate with PU.1 to regulate monocyte-specific genes.

c-Jun

The c-*jun* proto-oncogene encodes the transcriptional activator protein AP-1. As a member of the early response genes, c-*jun* is rapidly and transiently activated in response to external proliferative signals. The expression of c-Jun as well as related family members JunB and JunD is upregulated during monocytic differentiation. In addition, overexpression of c-Jun in M1, U937, or WEHI-B D^{+} myeloid cell lines, as well as in myeloid progenitor cells, was found to result in partial monocytic differentiation. However, $c\text{-}Jun^{-/-}$ fetal liver cells are capable of reconstituting hematopoiesis in syngeneic recipients, suggesting that c-Jun is not required for myeloid development. This finding may reflect a compensatory role played by other Jun family proteins.

As discussed, c-Jun serves as a coactivator of PU.1 during macrophage development. Recent studies have revealed that downregulation of c-jun by C/EBPα is necessary for granulocytic maturation and appears to be the mechanism through which C/EBPα blocks macrophage development (see Fig. 25-4). C/EBPα not only binds to the promoter of the c-jun gene and decreases its expression but also binds to PU.1, thereby inhibiting its activity. Such transcription factor cross-talk resulting in subtle changes in the levels of transcription factors within a given lineage appears to be an emerging paradigm through which master regulators of lineage specification, such as C/EBPα and PU.1, direct lineage-specific development by directly upregulating lineage-specific genes as well as by blocking the progression of alternate lineages.

Other Transcription Factors Modulating Monocyte Development

Egr-1. Egr-1 belongs to a family of zinc finger transcription factors and is expressed in a number of tissues and at various points in development, including the terminal stages of macrophage and neutrophil differentiation. Egr-1 is necessary for monocytic differentiation of myeloid cell lines U937 and M1 and prevents factor-induced granulocytic differentiation of HL60 and 32Dcl3 cells. Additionally, ectopic expression of Egr-1 in myeloid marrow progenitors was found to result in an increase in the number of CFU-M at the expense of CFU-G. However, mice lacking Egr-1 develop normal numbers of macrophages, a phenomenon attributed to the possible compensatory effects of other Egr family members.

C/EBPβ. As discussed, expression of C/EBPβ increases during myeloid maturation and has been shown to be important for monocyte/macrophage gene expression and development.

MafB and c-Maf. The transcription factors MafB and c-Maf belong to a family of basic-leucine zipper (b-Zip) factors that bind DNA as dimers. The Maf proteins can dimerize with members of other b-Zip family proteins, including c-Jun, fos, and NF-E2 in erythroid cells. Whereas ectopic expression of MafB in myeloblasts directed their expression to macrophages, overexpression of c-Maf in HL60 and U937 myeloid cells resulted in monocytic differentiation.

CHAPTER 26

THROMBOCYTOPOIESIS

Alan B. Cantor

Platelets, once regarded simply as "blood dust," are now recognized to play essential roles in hemostasis. Not only do they form a hemostatic plug and initiate thrombus formation in the event of vascular injury, but they also repair minute vascular damage that occurs on a daily basis. Platelets are also thought to be involved in wound healing and angiogenesis via delivery of key growth factors, such as VEGF, PDGF, and TGF-β to sites of vascular injury. Disorders associated with platelet production carry significant morbidity and mortality in humans due to hemorrhage, thrombosis, bone marrow fibrosis, bone marrow failure, and/or hematologic malignancy. Platelets are generated from their precursor cells, megakaryocytes, via a complex process. For a long time, the extreme rarity of megakaryocytes significantly hampered studies aimed at understanding the molecular mechanisms underlying platelet biogenesis. However, the purification and cloning (in 1994) of thrombopoietin (TPO), the major megakaryocyte cytokine, has enabled considerable progress to be made. These new insights provide an important foundation for improved diagnosis and treatment of disorders of thrombocytopoiesis. This chapter reviews the current understanding of megakaryocyte biology and platelet production, highlighting connections with human disease.

MEGAKARYOCYTE BIOLOGY

Megakaryocyte Development

Although platelets were described as early as the 1840s, it was not until 1906, in a seminal study by James Homer Wright, that their origin from megakaryocytes was first recognized.[1] Megakaryocytes are large polyploid cells that reside predominantly within the bone marrow during postnatal life. They are rare cells, constituting only about 0.1% of nucleated cells under normal steady-state conditions. They develop from common bipotential megakaryocyte-erythroid progenitor (MEP) cells, which are themselves derived from common myeloid progenitor (CMP) cells, and ultimately from pluripotential hematopoietic stem cells (HSCs). Once committed to the megakaryocytic lineage, megakaryocyte progenitors undergo a series or dramatic maturational steps ultimately tailored to their final task of platelet production and release. These include changes in proliferative capacity, cell size, nuclear content, organelle biogenesis, membrane development, and cytoskeletal rearrangement. The large increase in cell size is linked to an unusual process termed *endomitosis,* in which cells replicate their DNA but fail to undergo cytokinesis. Mature megakaryocytes reach diameters of approximately 100 microns and contain DNA content as high as 128N. They contain a multilobulated nucleus enclosed by a single nuclear membrane. Their abundant cytoplasm is filled with ribosomes, platelet-specific granules, mitochondria, and complex intracellular membrane systems. Although megakaryocytes reside predominantly within the bone marrow, they are also found in peripheral blood, spleen, and lung under normal conditions. These extramedullary megakaryocytes release platelets, but their contribution to total thrombocytopoiesis is estimated to account for at most 7% to 15%.

Megakaryocyte Progenitors

Like other hematopoietic progenitor cells, megakaryocyte progenitors can be cultured in vitro using semisolid media. Animal studies using these colony assays have allowed delineation of hierarchal developmental pathways of megakaryocyte progenitor maturation based on proliferative potential, DNA content, morphologic criteria, and gene expression pattern (Fig. 26-1). This pathway can be conceptually divided into three broad stages: proliferating megakaryocytic progenitors, which contain normal DNA content (2N/4N), nonproliferating immature megakaryocytes (4N-8N DNA content), and nonproliferating mature megakaryocytes (DNA content 8N-128N). Within the proliferating megakaryocyte progenitor compartment, the earliest detectable cell is the megakaryocyte high-proliferative-potential colony-forming cell (Mk-HPP-CFC), which is capable of generating macroscopically visible colonies containing a few thousand megakaryocytes. This corresponds to a proliferative capacity of ≈8 to 10 replicative cycles. These cells require IL-3 and simultaneous activation of the protein kinase C and cyclic adenosine monophosphate (cAMP) signaling pathway.

The burst-forming unit-megakaryocyte (BFU-Mk), which is thought to be a direct progeny of Mk-HPP-CFC, is more mature than the Mk-HPP-CFC, but retains a high degree of proliferative potential, developing "bursts" of individual colony-forming cells. These colonies contain approximately 100 to 500 megakaryocytes, representing ≈5 to 7 replicative cycles. In humans, BFU-Mk cells require mitogenic stimulation with IL-3 or GM-CSF and synergistic signaling with SCF (stem cell factor; also called *kit-ligand*), IL-11, IL-1α, and TPO. They are also resistant to treatment in vitro with 5-fluorouracil (5-FU).

The most mature proliferating cell is the colony-forming cell-megakaryocyte (CFU-Mk), which has very limited proliferative potential, representing only 2 to 5 cell divisions (4 to 32 megakaryocytes per colony). This progenitor responds to a variety of single growth factors, such as IL-3 and GM-CSF, and co-regulators such as SCF, FLT3 ligand, and TPO. They express early markers of differentiation such as glycoprotein IIb (GPIIb) and platelet factor 4 (PF4) before initiating endomitotic cell cycles.

Immature Megakaryocytes: Promegakaryoblasts

Promegakaryoblasts are transitional cells intermediate between proliferating progenitor cells and postmitotic, mature megakaryocytes. These cells are not readily observed morphologically in vitro or in bone marrow specimens but may be identified by their expression of megakaryocyte- or platelet-specific markers, such as platelet peroxidase, platelet GPIIb/IIIa, and von Willebrand factor (vWF). They have DNA content levels intermediate between proliferating progenitors and mature megakaryocytes. Promegakaryoblasts respond to a variety of cytokines in vitro, including IL-3, SCF, IL-6 and TPO, to produce large polyploid megakaryocytes. At least three distinct

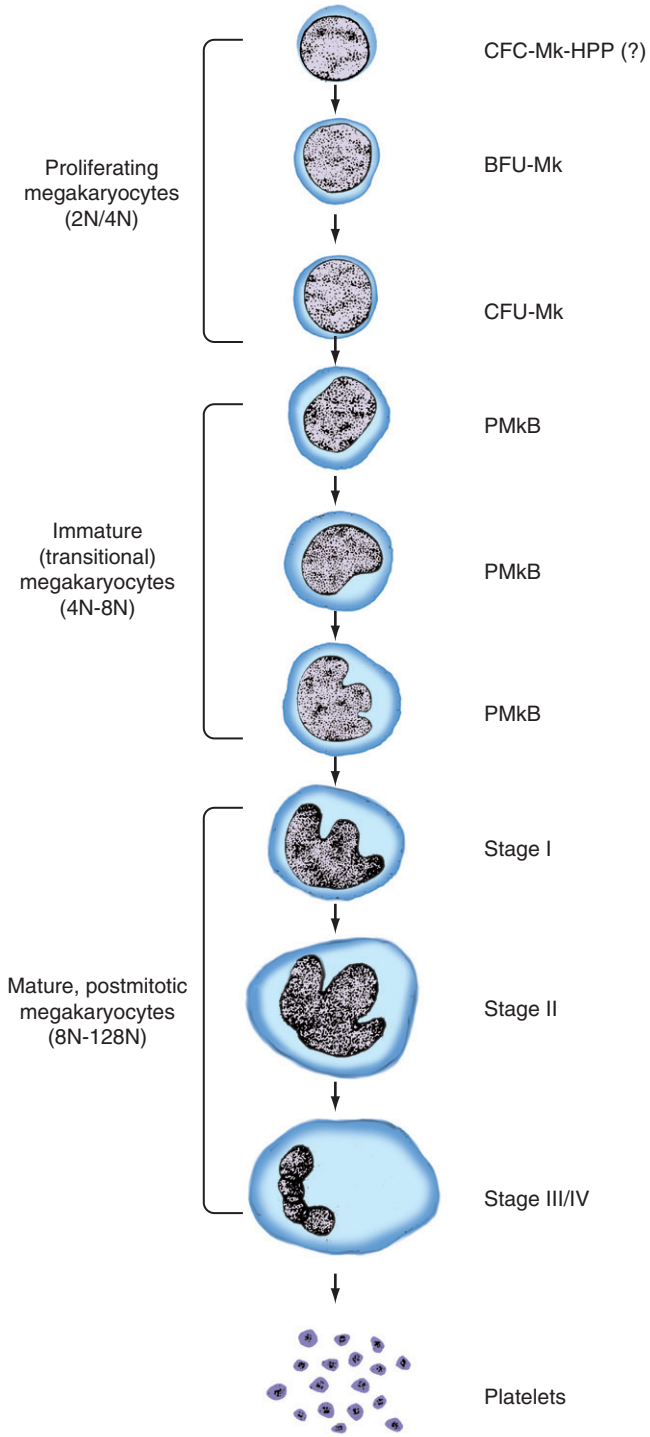

Figure 26-1 CELLULAR HIERARCHY OF MEGAKARYOCYTE DEVELOPMENT. Megakaryocyte development can be conceptually divided into three stages: The proliferating progenitor cells, which have the typical 2N/4N DNA content; the immature megakaryocytes, which have an intermediate DNA content and are transitional between the progenitor cells and the more mature cells; and the mature, postmitotic cells, which have an 8N to 128N DNA content. *BFU-Mk,* Burst-forming unit-megakaryocyte; *CFC-Mk-HPP,* colony-forming unit-megakaryocyte high-proliferative potential; *CFU-Mk,* colony-forming unit-megakaryocyte; *PMkB,* promegakaryoblast.

subpopulations of promegakaryoblasts have been identified based on different physiochemical characteristics, morphology, antigen expression, and enzyme content.

Mature Megakaryocytes

Morphologically recognizable megakaryocytes exist in at least four distinct maturation stages as defined morphologically (Fig. 26-2). The megakaryoblast (stage I) is characterized by a high nucleus-to-cytoplasm ratio and scanty basophilic cytoplasm, reflecting the large amount of protein synthesis occurring in these cells. The promegakaryocyte (stage II) is the cell in which the cytoplasmic volume and number of platelet-specific granules increase. The granular or "platelet shedding" megakaryocyte (stages III and IV) is the most mature cell. In reality, these stages likely represent a continuum.

Prospective Isolation of Megakaryocyte Progenitor Cells

Weissman and colleagues have reported the prospective isolation of clonogenic committed megakaryocyte progenitor cells from the bone marrow of adult C57BLKa-Thy1.1 mice based on selection of a unique cell surface immunophenotype: c-kit(+)Sca-1(-)IL7Ralpha(-)Thy1.1(-)Lin(-)CD9(+)CD41(+)FcgammaR(lo).[2] This fraction represents approximately 0.01% of the total nucleated bone marrow cells and gives rise to CFU-Mk and occasionally BFU-Mk in colony assays. The immunophenotype Lin(-)c-kit (+)Sca1(-)CD150 (+) CD41(+) has also been used to enrich for committed murine Mk progenitors. Identification of a comparable set of surface markers for human megakaryocyte progenitors has not been reported.

Structure of Mature Megakaryocytes

Mature megakaryocytes contain a large multilobulated polyploid nucleus often situated toward the periphery of the cell. They have abundant cytoplasm, which contains platelet-specific secretory granules, alpha (α-) granules and dense granules (Fig. 26-3).[3] The biogenesis of α-granules and dense granules begins in immature megakaryocytes, and both granule types develop concomitantly. α-Granules are 200 to 500 nm in diameter and have a dense center and fine granular matrix. Megakaryocytes synthesize many of the constituents of α-granules and target them to the granules. These include von Willebrand factor (vWF), fibronectin, P-selectin, fibrinogen receptors, platelet factor 4 (PF4), coagulation factor V, plasminogen activator inhibitor-1 (PAI-1), among others. In addition, some constituents, such as fibrinogen, are taken up by megakaryocytes via endocytosis and/or pinocytosis and stored in α-granules. It was once thought that α-granules were a homogeneous population of vesicles. However, it has become clear that there are distinct populations of α-granules containing different constituents, and these can be differentially released during platelet activation.[4] Dense granules are 200 to 300 nm in diameter and consist of a halo encircling an electron opaque core. They contain many soluble hemostatic factors such as serotonin, catecholamines, adenosine, adenosine 5′-diphosphate, adenosine 5′-triphosphate, and calcium. Their limiting membranes contain glycoproteins such as αIIbβ3, glycoprotein Ib (GPIb), and P-selectin, which are also present in α-granules, as well as unique membrane proteins such as granulophysin. Multivesicular bodies (MVBs) serve as intermediates in the biogenesis of both α-granules and dense granules. It has been proposed that they constitute a sorting compartment between α-granule and dense granule components.

The megakaryocyte cytoplasm contains at least two complex membranous systems: the demarcation membrane system (DMS) and the dense tubular network (DTS) (see Fig. 26-3). The DMS consists of an extensive network of tubular and flattened membranous structures that interconnect with one another and communicate

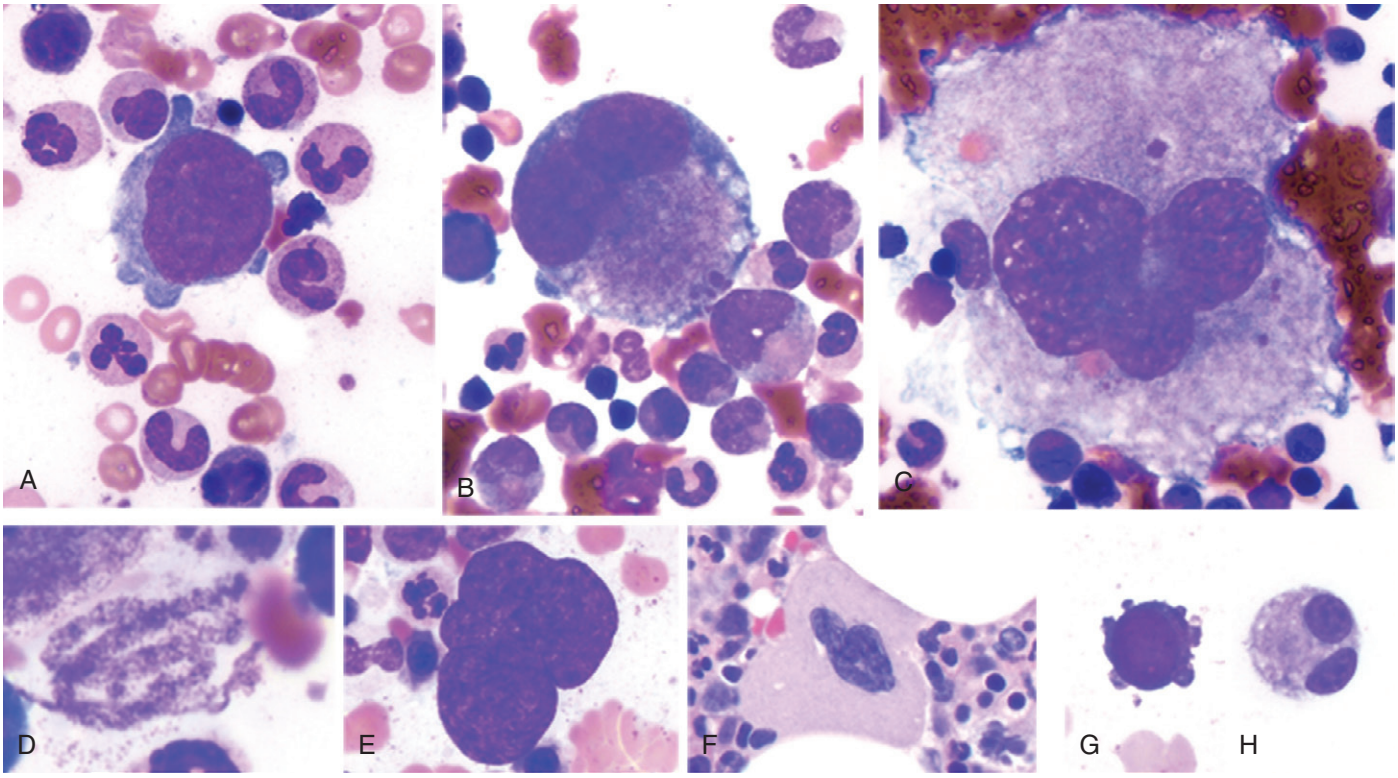

Figure 26-2 MEGAKARYOCYTOPOEISIS AND MEGAKARYOCYTES. **A,** Megakaryoblast (stage I) with intermediate ploidy level. Cytoplasm is scant. Note prominent cytoplasmic pseudopods. **B,** Promegakaryocyte with early platelet production (stage II). **C,** Mature, high-ploidy megakaryocyte (stage III or IV) with abundant cytoplasm. Note cells traveling through cytoplasm. This is referred to as *emperipolesis* and is not uncommonly seen in large megakaryocytes. **D,** Portion of megakaryocyte cytoplasm in a long strand. Fragments of these can sometimes be seen in the blood and are referred to as *proplatelets*. **E,** Megakaryocyte nucleus denuded of its platelets and cytoplasm. **F,** Mature megakaryocyte seen in a tissue section of bone marrow biopsy. **G,** Megakaryoblast from a patient with acute megakaryoblastic leukemia. Note cytoplasmic pseudopods. **H,** Micromegakaryocyte from a patient with myelodysplasia. Note small, low-ploidy (2-4N) nucleus, but mature cytoplasm.

with the extracellular space. Whole cell patch-clamp studies in living rat megakaryocytes show that they are electrophysiologically contiguous with the plasma membrane. The open canalicular system (OCS) of platelets shares many features of the megakaryocyte DMS and may represent a remnant of this structure. The DMS serves as a vast membrane reservoir for proplatelet and platelet formation. The DTS of megakaryocytes is distinct from the DMS. Unlike the DMS, it fails to stain with surface membrane tracer dyes, indicating a lack of communication with the plasma membrane. The DTS is thought to be a site of platelet prostaglandin synthesis.

Ontogeny of Megakaryopoiesis

Hematopoiesis develops in distinct waves during embryonic development.[5] In mammals, the first hematopoietic progenitors are found in blood islands of the yolk sac. These give rise to a distinct population of large erythrocytes, termed *primitive erythrocytes,* which express unique globin genes and retain their nucleus longer than adult-type or "definitive" erythrocytes. "Definitive" hematopoiesis arises later during embryogenesis from hematopoietic stem cells that develop de novo from the ventral aspect of the dorsal aorta in the aorto-gonad-mesonephros (AGM) region. These then seed the fetal liver, which serves as a major site of hematopoiesis during gestation. Eventually, hematopoiesis shifts to the bone marrow (and spleen in mice), where it is sustained postnatally.

Megakaryocyte progenitors have been detected in yolk sac as early as embryonic day 7.5 (e7.5) of mouse development.[6] They are capable of generating proplatelets and platelets after in vitro culture. Circulating platelets have been detected in the mouse embryo as early as e10.5. Megakaryocytes cultured from early yolk sac have features somewhat distinct from those cultured from adult bone marrow, such as lower modal ploidy, smaller size, different cytokine requirements, and faster kinetics of platelet generation. These unique progenitors disappear by e13.5. In addition, mixed erythroid-megakaryocyte colonies derived from the early yolk sac give rise to primitive erythrocytes. It has therefore been suggested that a separate wave of "primitive megakaryocytes," akin to "primitive erythrocytes," exists during early yolk sac stages of hematopoiesis. These rapidly maturing megakaryocytes may prevent hemorrhage from the developing vasculature until definitive hematopoiesis is available to provide a steady supply of platelets.

Several pieces of evidence suggest that fetal liver megakaryocytes also have unique features compared with adult bone marrow–derived megakaryocytes.[7] This could be due to either intrinsic differences in the progenitors, or possibly their interactions with a distinct microenvironment. Megakaryocytes that develop from murine neonatal liver progenitors after transplantation into myeloablated mouse recipients are smaller and have lower ploidy levels than those derived from transplanted adult bone marrow. However, these differences are no longer apparent 1 month after transplant. In addition, several congenital disorders of megakaryopoiesis in humans, such as Down syndrome transient myeloproliferative disorder (DS-TMD) and thrombocytopenia with absent radii (TAR) resolve spontaneously after the newborn period, suggesting specific effects on fetal megakaryocytopoiesis (see additional discussion of GATA1 mutations in DS-TMD later). It is possible that these differences account for the delayed platelet engraftment often observed when umbilical cord blood is used as a graft for allogeneic stem cell transplantation for humans.

Platelet Biogenesis

It has been estimated that each megakaryocyte produces between a few hundred to several thousand platelets. The exact mechanism by which this occurs has been controversial, with several competing models proposed in the past. It was initially suggested that the DMS established platelet fields, which defined territories of prepackaged platelet contents. These fields would generate platelets directly upon breakdown of the megakaryocyte cytoplasm. However, prevailing evidence supports an alternate model in which platelets are released from dynamic megakaryocyte pseudopod extensions called *proplatelets*. This model was first proposed by Becker and DeBruyn in 1976 and supported by ultrastructural studies later in the 1980s. Italiano and associates extended these earlier studies on proplatelet formation and platelet biogenesis using videomicroscopy of cultured murine megakaryocytes[8] (see Chapter 126). These in vitro experiments demonstrate that platelet biogenesis begins with a reorganization of unique cortical microtubules within the megakaryocyte to produce large pseudopodia structures from one pole of the megakaryocyte. This spreads across the megakaryocyte generating extensions that elongate into complex branching tubular proplatelet processes. During this time, organelles travel along microtubules within the shafts of the proplatelets and are loaded into the proplatelet tips where they are captured.[9] It is only at the tips of the proplatelet processes that platelets are shed. During proplatelet formation, extensive remodeling and branching occurs, allowing for marked amplification of proplatelet ends. This phenomenon likely accounts for the ability of each megakaryocyte to generate such a large number of platelets. The DMS serves as an extensive membrane reservoir for these processes.[10] Proplatelet formation is regulated by a pathway involving Rho GTPase proteins, Rho-associated kinase (ROCK), and the *MYH9* gene product myosin IIA.[11]

Bone Marrow Spatial Cues and Megakaryocyte Maturation

There is mounting evidence that the proliferation and terminal maturation of megakaryocyte progenitors occur in distinct spatial compartments within the bone marrow (see Chapter 9). In a simplified model, the bone marrow space can be conceptually divided into distinct regions, a space adjacent to the cortical bone (an "osteoblastic niche"), an intermediate zone, and a "vascular niche" containing sinusoidal vessels lined with specialized bone marrow endothelial cells (BMECs). HSCs are thought to reside in a quiescent state adjacent to the bone. Under appropriate conditions, they are recruited to generate hematopoietic multipotent progenitor cells, which leave the osteoblastic niche, perhaps in part under the regulation of metalloproteinases such as MMP-9. The multipotent progenitors are then subject to expansion and lineage commitment under the influence of various cytokines and likely other signaling molecules. This is where TPO is postulated to affect megakaryocyte progenitor proliferation and survival. Rafii and coworkers have shown that the chemokines stromal derived factor-1 (SDF-1; also called CXCL12) and fibroblast growth factor-4 (FGF-4) promote migration and attachment of murine megakaryocyte progenitor cells (which express the receptor for SDF-1, CXCR4) to the vascular endothelium, where they physically attach, mature, and produce intercalating pseudopod structures.[12] In fact, exogenous SDF-1 and FGF-4 restores thrombopoiesis in $TPO^{-/-}$ or TPO receptor $(c\text{-}Mpl)^{-/-}$ mice to near wild-type levels. This occurs in the absence of enhanced megakaryocyte progenitor proliferation and requires direct physical interaction with BMECs. Based on these findings, Rafii and colleagues have proposed a model in which megakaryocyte progenitors proliferate in an immature developmental state (in response to TPO) in a nonvascular niche (Fig. 26-4). However, once the progenitors reach and adhere to the sinusoidal vessels in the vascular niche in response to chemokines (Fig. 26-5), proliferation ceases and terminal maturation and platelet release ensues. Work from other investigators supports this model. Multiple electron microscopic studies have captured megakaryocytes extending proplatelet processes through vascular endothelium and into bone marrow sinusoids, and a recent in vivo imaging study documented this process in living mice.[13] Isolated megakaryocytes can be induced to form proplatelets after adhering to bovine corneal endothelial cells-derived extracellular matrix or via binding of the megakaryocyte surface integrin $\alpha IIb\beta 3$ to fibrinogen, which is present in bone marrow vascular sinusoids. Conversely, culture of megakaryocytes with bone marrow stromal cells inhibits megakaryocyte differentiation.

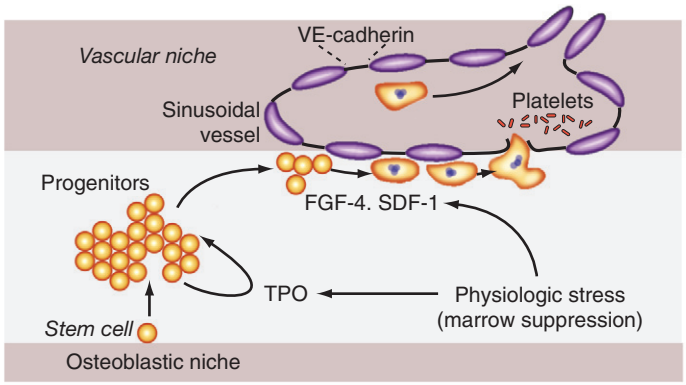

Figure 26-4 MODEL OF TERMINAL MATURATION OF MEGAKARYOCYTES AT THE BONE MARROW VASCULAR SINUSOID. Schematic diagram showing hematopoietic stem cells (HSCs) located predominantly adjacent to the cortical bone ("osteoblast niche"), megakaryocyte progenitors proliferating in the bone marrow space, and migration of progenitor cells to the vascular sinusoid ("vascular niche") under the influence of chemokines such as SDF-1 and fibroblast growth factor 4 (FGF-4). Once attached to the sinusoidal vascular endothelium, megakaryocyte progenitors cease proliferating, undergo terminal maturation and proplatelet formation, and shed platelets into the vascular sinusoidal space. *(From Avecilla ST, Hattori K, Heissig B, et al: Chemokine-mediated interaction of hematopoietic progenitors with the bone marrow vascular niche is required for thrombopoiesis,* Nat Med *10:64, 2004. Reproduced with permission.)*

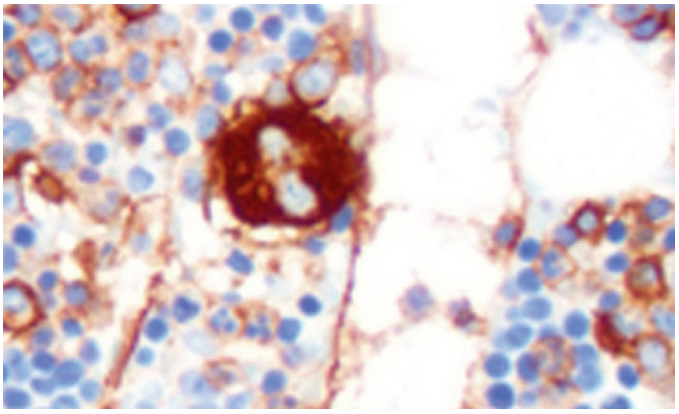

Figure 26-5 MEGAKARYOCYTE ATTACHED TO SINUSOIDAL VASCULAR ENDOTHELIUM. Bone core biopsy with megakaryocyte (stained with CD31) attached to the endothelium of a sinusoidal vessel *(right)*.

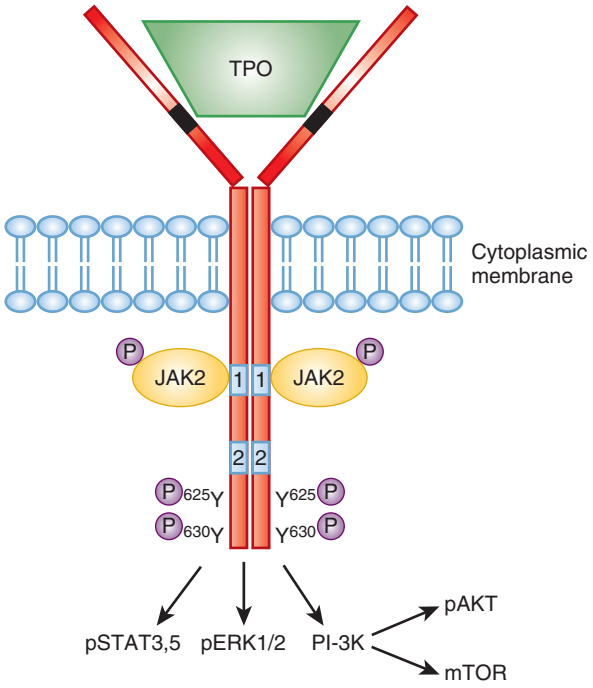

Figure 26-6 THE THROMBOPOIETIN RECEPTOR. Schematic diagram of the TPO receptor depicted as a homodimer with TPO bound. Binding of JAK2 at box 1 of the cytoplasmic tail is shown. Conformational changes in the TPO receptor upon TPO binding results in juxtaposition of the two cytoplasmic tails, as well as JAK2 autophosphorylation and JAK2-mediated phosphorylation of the c-Mpl cytoplasmic tail (Tyr^{625} and Tyr^{630}). Activation of STAT, ERK, phosphoinositol-3 kinase (PI-3K)-Akt, and PI3K- mTOR signaling pathways then occurs. *(Modified from Geddis AE: Megakaryopoiesis,* Semin Hematol *47:212, 2010.)*

CYTOKINE REGULATION OF THROMBOCYTOPOIESIS

Thrombopoietin Signaling

Thrombopoietin

It has been estimated that an adult human produces nearly 2×10^{11} platelets per day, and this number can increase four- to eight-fold during times of increased demand.[14] The regulation of this process has been the subject of intense investigation. Kelemen first used the term *thrombopoietin* in 1958 to describe a humoral substance responsible for enhancing platelet production following the onset of thrombocytopenia. However, it was not until 1994 that five independent groups succeeded in purifying and cloning the responsible cytokine, now known as thrombopoietin (TPO) (previously referred to as *c-Mpl ligand, megakaryocyte growth and development factor [MGDF],* and *megapoietin*).[15] The gene for thrombopoietin is located on chromosome 3q27. It encodes a 30 kDa glycoprotein of 353 amino acids that can be divided into two structural domains: an amino terminal region with homology to human erythropoietin, and a carboxyl terminal region that contains multiple N- and O-linked oligosaccharides. The amino terminal 155 residues of human thrombopoietin share 21% sequence identity and 46% overall sequence similarity to human erythropoietin. This region mediates binding to the TPO receptor (c-Mpl). The carboxyl region does not share sequence homology with any known protein. Thrombopoietin is reported to enhance multiple stages of megakaryocyte maturation, including cell size, cell ploidy, and platelet production. The predominant sites of TPO production are the liver and kidney, which secrete it constitutively. Inducible expression of TPO has been detected by more sensitive methods in bone marrow stroma and spleen in the setting of thrombocytopenia, although this likely accounts for only a minor fraction of total TPO production. Low-level expression has also been reported in the amygdala and hippocampus of the brain.

Thrombopoietin Receptor (c-Mpl)

The receptor for TPO (TPO receptor; c-Mpl) is the normal homologue of the oncogene v-Mpl, the transforming gene of murine myeloproliferative leukemia virus. It is a 635 amino acid protein that contains a number of distinct functional domains: a 25 amino acid signal peptide, a 465 amino acid extracellular domain, a 22 residue transmembrane domain, and an intracellular domain that contains two conserved motifs, termed *box 1* and *box 2* (Fig. 26-6). The extracellular domain contains of a distal region that negatively influences TPO signaling. It is a member of the type I cytokine receptor superfamily. Like the erythropoietin receptor, it is thought to function as a homodimer. The TPO receptor is expressed on megakaryocyte

progenitors, as well as earlier multipotential progenitors, including MEPs, CMPs, and HSCs. TPO receptors are present on the surface of platelets at an estimated density of 20 to 200 receptors per platelet and bind TPO with an affinity of 200 to 560 pM. Binding of TPO to platelets plays an important role in the regulation of total body platelet mass by the TPO-TPO receptor system. Both TPO receptor$^{-/-}$ (c-Mpl$^{-/-}$) and TPO (TPO$^{-/-}$) knock-out mice contain ≈85% to 90% lower platelet and megakaryocyte numbers as compared with wild-type mice.[16,17] The structure of the megakaryocytes and platelets in these animals is normal, reinforcing the notion that TPO signaling plays an important role in expansion and development of megakaryocyte progenitors, but not in terminal maturation and proplatelet release. In addition, the residual platelet production in these mice suggests alternate cytokine, or possibly cytokine-independent, pathways for thrombocytopoiesis. Interbreeding experiments of TPO receptor$^{-/-}$ mice with knock-out mice for IL-3, IL-6, IL-11, or LIF or their receptors, show that these other cytokines are not responsible for the residual platelet production.

TPO Receptor Downstream Signaling Pathways

The TPO receptor lacks intrinsic tyrosine kinase activity. Instead, ligand binding is thought to induce a conformational change in the homodimeric receptor and stimulates the cytoplasmic tyrosine kinase JAK2 (Janus-kinase 2), which binds to box 1 of the cytoplasmic tail. This results in tyrosine phosphorylation of multiple targets, including STATs (signal transducers and activators of transcription), Shc adaptor protein, and the TPO receptor itself (Tyr^{625} and Tyr^{630}).[18] Additional signaling pathways activated upon TPO receptor engagement include the mitogen-activated protein kinase (MAPK) p38, p42/p44 extracellular signal-regulated kinase 1 (ERK1/ERK2), phosphoinositol-3-kinase-AKT (PI3K-AKT), and PI3K-Mammalian target of rapamycin (mTOR) signaling pathways.

Several of these downstream signaling pathways have been shown to be functionally important in TPO-mediated effects on megakaryocytopoiesis. Double STAT5a/STAT5b–deficient mice have impaired platelet production as well as defects in early multipotent progenitor cells. Moreover, megakaryocyte-selective overexpression of a dominant negative mutant STAT3 in transgenic mice reduces platelet recovery following 5-fluorouracil–induced myelosuppression. These findings suggest a functional role for STAT family members in thrombopoiesis.

Studies in primary megakaryocytes show a requirement for PI3-AKT signaling in TPO-induced cell cycling. This involves silencing of the Forkhead O (FOXO) family of transcription factors. Activation of the p42/p44-MAPK plays an important role in TPO-induced maturation and endomitosis. The mTOR signaling pathway is involved in TPO-mediated megakaryocytic progenitor proliferation and possibly terminal megakaryocyte size determination, ploidy, and cellular maturation.[19]

Negative Regulation of TPO Signaling

As with other receptor-mediated signaling processes, feedback mechanisms exist to limit or turn off the signal once initiated to avoid uncontrolled growth. Lnk, an adaptor protein implicated in immunoreceptor and cytokine receptor signaling negatively modulates TPO signaling in megakaryocytes. Overexpression of Lnk decreases TPO-dependent megakaryocyte growth and polyploidization in bone marrow (BM)–derived cultures. Conversely, loss of Lnk expression by gene targeting results in increased numbers of megakaryocytes, accentuated megakaryocyte polyploidization, and a myeloproliferative disorder in mice.[20] This correlates with enhanced and prolonged TPO-mediated induction of STAT3, STAT5, AKT, and MAPK signaling pathways.

Following TPO binding, the TPO receptor is internalized and subsequently degraded. This process depends on dileucine repeats, and Tyr^{591} and Tyr^{625} within the TPO receptor cytoplasmic tail, and involves ubiquitinylation via the E3 ubiquitin ligase c-Cbl.

TPO Signaling in Hematopoietic Stem Cells

It has recently been recognized that the TPO-TPO receptor signaling system is not only important for megakaryocyte proliferation and development, but also plays a role in hematopoietic stem cell survival, self-renewal, and expansion.[21] TPO receptor$^{-/-}$ HSCs compete poorly with wild-type HSCs, even at a ratio of 10:1, in murine bone marrow competitive repopulation studies. The role of TPO signaling in HSC expansion is in part due to its activation of the homeobox domain containing transcription factor HOXA9, via a mechanism involving phosphorylation and nuclear translocation of its partner protein MEIS1.

Congenital Amegakaryocytic Thrombocytopenia

Bi-allelic mutations in the TPO receptor gene cause congenital amegakaryocytic thrombocytopenia (CAMT) (see Chapter 27). In this disorder, megakaryocytes are absent or greatly diminished in number in the bone marrow. Patients typically present shortly after birth with petechiae, bruising, or bleeding. Patients with severe CAMT are at high risk for developing progressive bone marrow failure, typically within the first few years of life. This is consistent with a role of TPO signaling in maintaining hematopoietic stems cells and/or multipotential progenitor cells. Of interest, no mutations in the gene encoding TPO itself have been reported in patients with CAMT. It should also be noted that in contrast to the humans, TPO receptor$^{-/-}$ (as well as TPO$^{-/-}$) mice do not develop bone marrow failure states. The reason for this discrepancy is not known, but it highlights important differences between human and mouse hematopoiesis.

Essential Thrombocythemia

Essential thrombocythemia (ET) is a chronic myeloproliferative neoplasm associated with sustained excessive megakaryocyte hyperproliferation, thrombocytosis, and abnormal platelet function leading to either hemorrhage or thrombosis (see Chapter 68). In 2005, an acquired activating mutation in the JAK2 family (V617F JAK2) was identified by four independent groups in a large proportion (≈50%) of patients with ET. The identical mutation has also been identified in several other myeloproliferative neoplasms, including polycythemia vera (95% of patients) and primary myelofibrosis (50% of patients). How the identical mutation leads to distinct clinical entities is not well understood but may be related to the allelic dosage of the mutation. Mutations leading to constitutive activation of the TPO receptor or enhanced translation efficiency of the TPO gene have also been reported in rare cases of familial thrombocytosis. These two classes of disorders can be distinguished by measuring circulating TPO levels, which are elevated with mutations enhancing TPO mRNA translation efficiency, and decreased with mutations leading to constitutive TPO receptor activation (see Chapter 68).

Regulation of Platelet Mass by Thrombopoietin

Platelet counts are typically held at a relatively fixed level in humans, ranging from 150,000 to 400,000/mm^3. The maintenance of platelet number by the TPO-TPO receptor system involves an unusual homeostatic mechanism among hematopoietic cytokine-mediated regulation. This is sometimes referred to as the "sponge" model (Fig. 26-7). Unlike other cytokines, TPO is secreted predominantly in a constitutive manner, mostly from the liver and kidney. High affinity TPO receptors present on the platelet surface bind free TPO and internalize it, where it is degraded. Therefore, when platelet counts are low, less TPO is removed, and more is available to stimulate megakaryocytopoiesis in the bone marrow. Conversely, when platelet counts rise above a given set point, they act as a "sink" for TPO, binding and destroying it before it can stimulate megakaryocytopoiesis in the bone marrow. Thus total platelet mass is preserved,

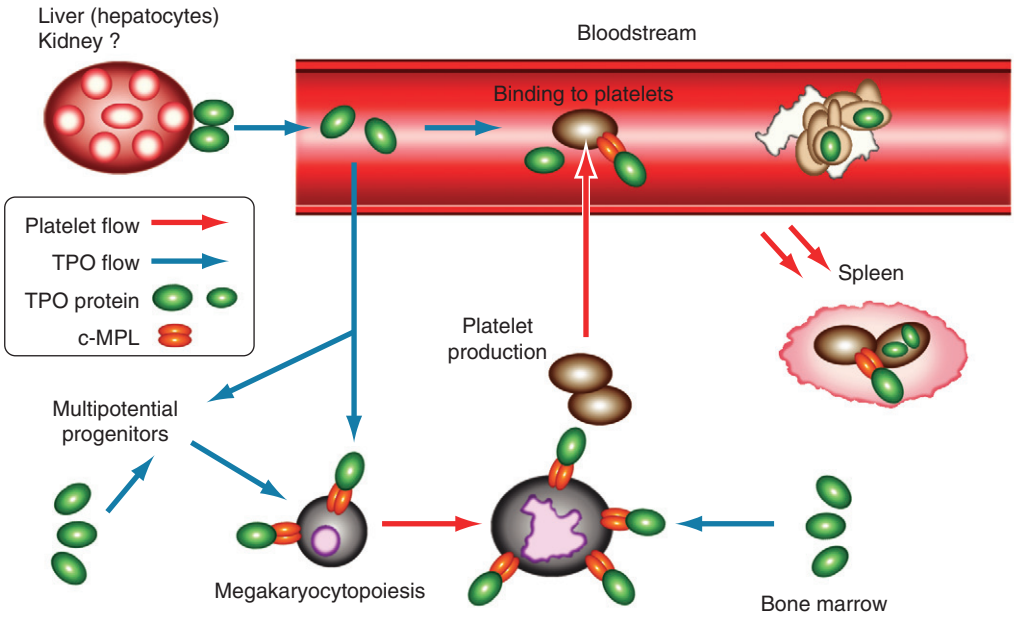

Figure 26-7 REGULATION OF PLATELET COUNT BY THROMBOPOIETIN: THE "SPONGE" MODEL. Thrombopoietin is secreted at a constitutive rate primarily from liver, and perhaps other sources such as the kidney, into the circulation. There it binds with high affinity to TPO receptors (c-Mpl) present on the surface of platelets. The TPO is then internalized by the platelets and degraded. Free TPO (i.e., TPO not bound to platelets) enters the bone marrow and stimulates megakaryocytopoiesis. Thus in the presence of high platelet counts, little free TPO is available to stimulate megakaryocytopoiesis. Conversely, low platelet numbers lead to increased free TPO and active megakaryocytopoiesis. The net result is preservation of total platelet mass.

rather than absolute platelet number. This may explain the mild-moderate thrombocytopenia seen in certain disorders associated with large platelets, such as Bernard-Soulier syndrome (BSS).

Several pieces of evidence support this model. First, it has been known for over 40 years that the peripheral blood platelet count varies inversely with plasma TPO activity. Second, TPO receptor deficient mice (c-Mpl$^{-/-}$) have elevated levels of circulating TPO, and this is reduced when the mice are transfused with washed platelets from normal mice. Third, in contrast to platelets from TPO receptor–deficient mice, platelets from normal mice bind purified radiolabeled TPO and degrade it. Fourth, TPO levels are low to intermediate in normal individuals and in those with idiopathic thrombocytopenic purpura (where the bound TPO is destroyed along with the platelets). However, following chemotherapy, or in individuals with aplastic anemia, levels are markedly elevated.

Although the model described above likely explains the predominant basal regulation of platelet number by the TPO-TPO receptor signaling system, overlying inducible mechanisms also probably exist. It has been shown that the TPO gene is transcriptionally activated in bone marrow stroma and spleen during times of thrombocytopenia, although the degree to which this may contribute to total TPO levels is uncertain. In addition, IL-6 mediates up regulation of hepatic TPO mRNA transcripts in inflammation-related thrombocytosis.

Additional Cytokines Involved in Megakaryocytopoiesis

Although TPO is the major cytokine regulating megakaryocytopoiesis, other cytokines have been shown to be active in vitro, particularly during earlier stages of megakaryocyte development. These include SCF, IL-3, IL-6, IL-11, leukemia inhibitory factor (LIF), G-CSF, and erythropoietin (EPO). None of these factors are megakaryocyte-specific, but act as synergistic co-regulators with TPO. Only SCF and TPO have been shown to affect megakaryocyte development and platelet production in vivo using genetic ablation experiments in mice. No effects were seen with knockout of IL-3, IL-6, IL-11 receptor, or LIF.

Therapeutic Cytokine Stimulation of Megakaryocytopoiesis

Since the identification of TPO as a major activator of megakaryocyte growth and maturation, there has been considerable interest in developing recombinant forms of TPO for clinical use in the treatment of chemotherapy-related thrombocytopenia and immune-mediated thrombocytopenia. Small pilot studies using a polyethyleneglycol (PEG)ylated, truncated form of human TPO (PEG-MGDF) showed activity in stimulating megakaryocyte growth and maturation, resulting in elevated platelet counts. However, some recipients subsequently developed thrombocytopenia as a result of the generation of a neutralizing anti-TPO antibody that cross-reacted with endogenous TPO. The agent was therefore withdrawn from further testing. Since then, several nonimmunogenic thrombopoietic peptides and small, nonpeptide molecules have been developed.[22] Romiplostim (formerly called *AMG 531*), a synthetic molecule consisting of an immunoglobulin Fc domain fragment linked to two identical peptide chains that activate the TPO receptor, stimulates platelet production and has been approved by the Food and Drug Administration (FDA) for the treatment of adults with chronic immune thrombocytopenia purpura (ITP). It is given intravenously or subcutaneously. Eltrombopag, an orally administered small molecule that binds to a portion of the TPO receptor distinct from the normal TPO binding site, also stimulates thrombopoiesis and is FDA approved for the treatment of chronic ITP. Additional agents that stimulate the TPO receptor are also under development.

IL-11 has multiple effects on in vivo and in vitro megakaryocytopoiesis. It affects IL-3–dependent megakaryocyte colony formation and has a potent effect on megakaryocyte maturation. Administration of recombinant IL-11 to mice results in increased numbers of megakaryocyte progenitors, increased megakaryocyte polyploidization,

and increased peripheral platelet counts. Recombinant IL-11 has been approved for use in humans for the treatment of chemotherapy-induced thrombocytopenia.

ENDOMITOSIS

The Endomitotic Cell Cycle

Megakaryocytes derive their name from their large and complex nuclei. This arises from an atypical cell cycle, termed the *endomitotic* cell cycle (see comprehensive review by Ravid and colleagues[23]) (Fig. 26-8). Like normal diploid cells, the cycle begins with a G1 phase, followed by S phase (DNA replication), and a G2 phase. The cells then enter M phase, but unlike normal diploid mitotic cells, fail to complete anaphase B, telophase, or cytokinesis. A cleavage furrow initially develops but then regresses. The cells then proceed directly to the next G1 phase and subsequent rounds of DNA replication. As DNA ploidy increases, multiple spindle poles and centrosomes form, but chromosome segregation is incomplete and asymmetric. During each endomitotic cell cycle (Fig. 26-9), the nuclear envelope breaks down and later reforms as a single nuclear membrane around all of the sister chromatids. The end result is a polyploid cell with a multilobulated nuclei encapsulated by a single nuclear membrane. Mature human megakaryocytes have been observed to reach ploidy levels as high as 128N. The term *endoreduplication* has at times been used

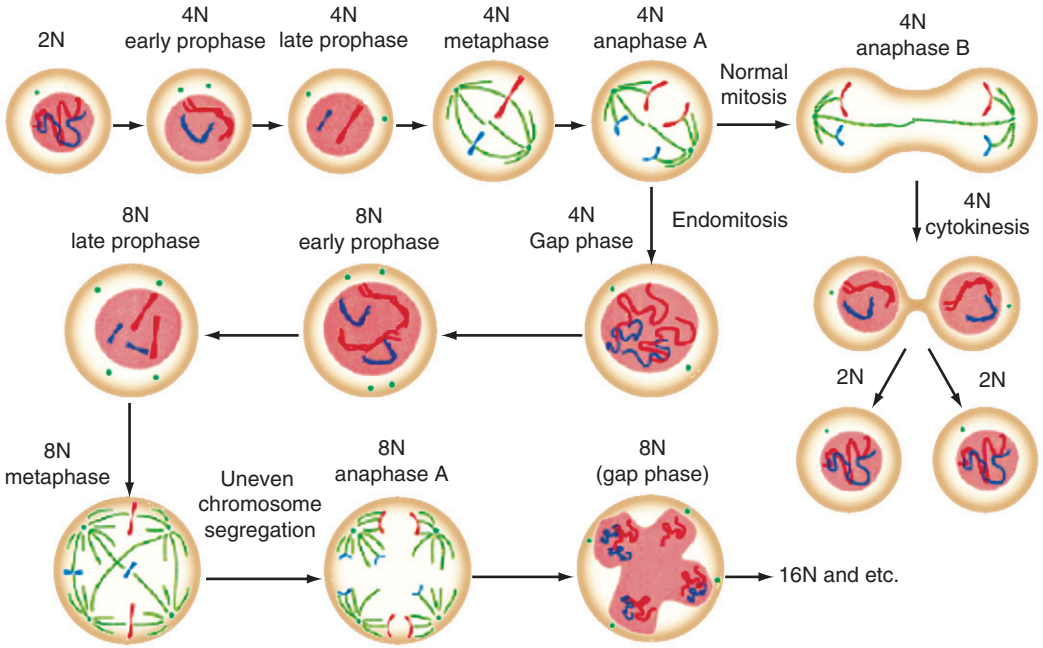

Figure 26-8 THE ENDOMITOTIC CYCLE IN MEGAKARYOCYTES. Schematic diagram depicting stages of the cell cycle in cells undergoing endomitosis *(bottom left)* versus normal mitosis *(right)*. Endomitotic and mitotic cells share all stages of the cell cycle until anaphase A. Normal mitotic cells proceed through anaphase B and complete cytokinesis, yielding two daughter cells, each with 2N DNA content. In contrast, endomitotic cells fail to undergo anaphase B or cytokinesis, and proceed to the next cycle following a gap phase. Subsequent rounds produce multicentric spindles with uneven chromosome segregation. A single nuclear membrane *(shown in pink)* reforms after each round of endomitosis. Centrosomes are shown as *blue dots*. *(From Ravid K, Lu J, Zimmet JM, et al: Roads to polyploidy: The megakaryocyte example,* J Cell Physiol *190:7, 2002. Reproduced by permission.)*

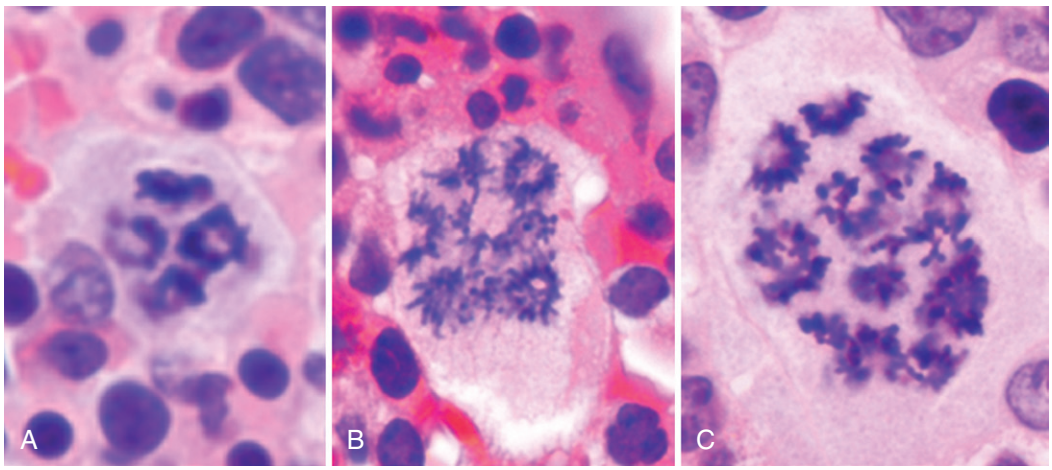

Figure 26-9 MEGAKARYOCYTES IN ENDOMITOSIS. Polyploid megakaryocytes in endomitosis at 8N stage **(A),** 16N stage **(B),** and probably 32N stage **(C).**

erroneously to describe megakaryocyte polyploidization. *Endoreduplication* correctly refers to a cell cycle that involves DNA replication but no entry into M phase.

Role of Endomitosis in Thrombocytopoiesis

The reason that megakaryocytes undergo endomitosis is not known. It has been speculated that it provides a means for generating the abundant membrane, protein, biosynthetic cargo, and energy required for the dramatic final stages of proplatelet elaboration and platelet release. Several circumstantial pieces of evidence support this model. First, it is known that megakaryocyte DNA content correlates with megakaryocyte cell size, mRNA content, protein production, and eventual numbers of platelets released. Second, an increased DNA content of megakaryocytes precedes increases in platelet count during recovery from acute thrombocytopenia. Third, increases in cytoplasmic volume and maturation occur predominantly, if not completely, in stage II and III megakaryocytes, which do not synthesize DNA. Fourth, in polyploid megakaryocytes (4N to 32N), all alleles of the genes studied (i.e., ITGA2B [GPIIb], VWF, ACTB [β-actin], HSPA1 [HSP70], MPL, FLI1, and ZFPM1 [FOG-1]) have been found to be transcriptionally active.

Mechanisms of Endomitosis in Megakaryocytes

The molecular mechanisms mediating endomitosis in megakaryocytes are incompletely understood. Studies investigating endomitosis have been hampered by the rarity of megakaryocytes, difficulty separating direct effects from general perturbations of cell maturation, complications associated with synchronizing the cell cycle, use of transformed cell lines, and potential differences between rodent and human megakaryocytes.

Cyclins and Cyclin-Dependent Kinases

Two classes of proteins control the cell cycle in mammalian cells. These are the cyclins, so named for their cyclical synthesis and degradation during the cell cycle, and cell division kinases (Cdks, also known as *cyclin-dependent kinases*). Together, these two families of proteins form a protein-kinase complex in which the regulatory unit is the cyclin and the catalytic unit is the Cdk. The role of these kinase complexes in cell cycle control is complex. At least seven members of the cyclin gene family and seven distinct Cdk genes have been identified.

Given the importance of cyclins and Cdks in controlling cell cycle, they have been the focus of considerable attention in investigations of the mechanisms underlying megakaryocyte endomitosis. The most compelling evidence probably exists for a role of the D-type cyclins in megakaryocyte endomitosis. The D-type cyclins are unique in that their activity can be modulated by extracellular mitogens. Megakaryocytes express cyclin D3 and, to a lesser extent, cyclin D1. Levels of both of these factors increase after treatment with TPO. Overexpression of cyclin D3 results in increased megakaryocyte ploidy in transgenic mouse models. Complexes of cyclin D3 and its major kinase subunit, Cdk2, show high kinase activity in polyploid cells. Antisense knockdown of cyclin D3 levels suppresses endomitosis and abrogates normal development of primary mouse megakaryocytes.

Cyclin D1 is a direct target gene of GATA1, a transcription factor required for megakaryocyte polyploidization and maturation. Overexpression of cyclin D1 in transgenic mice increases megakaryocyte modal ploidy compared with nontransgenic littermates, and the combination of cyclin D1 and Cdk4 kinase activity restores polyploidization of GATA1-deficient murine megakaryocytes. Conversely, enforced expression of $p16^{ink4a}$, a cell cycle inhibitor of Cdk4/6, blocks polyploidization in murine megakaryocytes. $p16^{ink4a}$ is also potently repressed by GATA1.

Cyclin $E^{-/-}$ mice have impaired megakaryocytopoiesis with reduced modal ploidy. These mice also have defective trophoblast development, another tissue characterized by endomitosis. Cyclin B1/CDC2 is a mitotic cyclin complex. Yeast strains deficient in cyclin B1 or CDC2 undergo an additional round of DNA replication without cytokinesis. Several studies have shown that low levels of cyclin B1/CDC2 are required for progression of endomitosis in megakaryocytic cell lines. However, studies of primary megakaryocytes have shown normal cyclin B1 and CDC2 levels and functional mitotic activity during endomitosis.

Other Mitotic Kinases

Aurora-B kinase (also called *AIM-1 kinase*) is involved in late anaphase and cytokinesis, and mRNA transcript levels of Aurora-B kinase have been reported to decrease during polyploidization of primary megakaryocytes and megakaryocytic cell lines. This suggests that Aurora-B kinase may play a mechanistic role in megakaryocyte endomitosis. However, functional activity of Aurora-B kinase appears normal in late anaphase of endomitotic primary megakaryocytes, indicating that simple deficiency of Aurora-B kinase activation is an unlikely mechanism to explain endomitosis. Polo-like kinase (PLK-1) is a serine-threonine kinase required for assembly of the mitotic spindle, separation of chromosomes during anaphase, and exit from mitosis. PLK-1 mRNA and protein levels decrease during polyploidization of murine megakaryocytes, and enforced expression of PLK-1 in primary murine megakaryocytes impairs endomitosis. However, the effects of overexpression are modest, preferentially affect lower-ploidy megakaryocytes, and are complicated by alterations in cell cycle kinetics.

The Spindle Checkpoint

During mitosis of normal diploid cells, a spindle assembly checkpoint prevents progression of anaphase until all of the chromosomes are aligned with the mitotic spindle and each sister chromatid is properly attached to spindle microtubules originating from the opposing spindle pole. This ensures that each daughter cell receives the proper complement of chromosomes. The anaphase-promoting complex (APC) is a multisubunit protein complex with ubiquitin ligase activity that regulates chromosome segregation and anaphase progression by targeting key factors for degradation. Since some chromosomal missegregation occurs during megakaryocyte endomitosis, several groups have examined the expression levels and/or activity of certain APC components and associated factors. These studies have shown no significant difference in protein levels of the core APC protein CDC27 or the kinetochore-associated signaling protein hsMAD2 in primary murine megakaryocytes undergoing polyploidization compared with nonendomitotic precursors. Haploinsufficiency of BUBR1, a key component of the spindle checkpoint, perturbs megakaryocyte development and polyploidization in mice, but does not cause alterations in circulating platelet counts.

Microtubule Regulation

Microtubules play key roles in mitosis. Therefore factors that regulate their assembly have also been investigated as candidates involved in megakaryocyte endomitosis. PRC-1 is involved in mitotic spindle elongation and cytokinesis. However, no differences in PRC-1 levels were detected in primary murine megakaryocytes undergoing polyploidization compared with nonendomitotic precursors. Stathmin is a microtubule-depolymerizing factor that plays an important role in regulation of the mitotic spindle. Levels of stathmin are inversely related to the level of ploidy of megakaryocytic cell lines and primary megakaryocytes. Inhibition of stathmin in K562 cells increases their propensity to undergo endomitosis when induced to differentiate into megakaryocytes, and overexpression of stathmin prevents the transition from mitotic to endomitotic cell cycles. Together,

these findings support a possible role of stathmin in modulating endomitosis.

Contractile Ring Activity

Cytokinesis requires the assembly and activity of a contractile ring. The failure to complete cytokinesis during endomitotic cell cycles in megakaryocytes may involve functional defects in the Rho/Rock pathway.[24] Further studies will be required to fully dissect the molecular pathways involved in megakaryocyte endomitosis.

TRANSCRIPTIONAL CONTROL OF MEGAKARYOCYTOPOIESIS

Since platelets do not contain nuclei, all transcriptional regulation of platelet-specific genes must occur at the level of the megakaryocyte. Significant strides have been made recently in identifying key transcription factors involved in megakaryocyte development and platelet-specific gene expression. Of note, mutations in several of these factors have been linked to various hematologic disorders providing significant new insights into the pathogenesis of these diseases (see Chapters 4 and 152; see also box on Inherited Causes of Thrombocytopenia.

GATA Family Transcription Factors

GATA1

GATA transcription factors comprise a family of zinc finger proteins that bind the consensus DNA sequence (T/A))GATA(A/G). There are six known members of the GATA family in vertebrates. GATA1, -2, -3 play roles predominantly, although not exclusively, within the hematopoietic system. GATA4, -5, and -6 are expressed in nonhematopoietic tissues and play diverse developmental roles within the cardiac, gastrointestinal, endocrine, and gonadal systems. Functionally important binding sites for GATA factors have been identified in cis-acting regulatory elements of essentially every megakaryocytic and erythroid gene that has been studied. GATA1, the founding member of this family, is highly expressed in erythroid and megakaryocytic cells and, to a lesser extent, in eosinophils and mast cells. GATA1 plays an essential role in erythroid development, with loss of function resulting in blocked erythroid maturation and apoptosis of erythroid progenitor cells. GATA1 is also required for megakaryocyte maturation and growth control. Lineage-selective loss of GATA1 in megakaryocytes results in marked thrombocytopenia in mice with platelet counts of only ≈15% of wild-type littermates. Megakaryocytes are present in the mutant animals but have a disorganized DMS, paucity of platelet-specific granules, reduced expression of multiple megakaryocyte-specific genes (including GPIbα, GPIbβ, PF4, c-Mpl, and p45 NF-E2), and marked hyperproliferation as compared with wild-type mice. Gene expression studies of GATA1-deficient versus wild-type murine megakaryocytes have revealed a large number of potential GATA1 target genes, although evidence for direct targets has only been established for a few. Mice containing reduced megakaryocyte-specific expression of GATA1 ($GATA1^{low}$) develop myelofibrosis as they age, a frequent finding with disorders of megakaryocyte progenitor hyperproliferation. A GATA binding site mutation in the GPIbβ promoter has been described in a patient with Bernard-Soulier syndrome, which is characterized by deficiency of the GPIb/IX/V complex and a bleeding diathesis. Taken together, these findings suggest that GATA1 acts as master regulator of megakaryocyte maturation and proliferative control.

Friend of GATA (FOG-1)

All vertebrate GATA factors contain two zinc fingers. The carboxyl zinc finger mediates high-affinity DNA binding, whereas the amino zinc finger stabilizes the DNA interaction at certain double GATA sites. Important to note, the amino zinc finger also interacts with Friend of GATA (FOG) proteins, a family of large multitype zinc finger transcriptional cofactors. This interaction occurs on the surface of the zinc finger opposite to its DNA binding surface. FOG-1 (also called zfpm1), the founding member, is expressed predominantly within erythroid and megakaryocytic cells. Knockout of FOG-1 in mice results in embryonic lethality caused by severe anemia from a block in erythroid maturation similar to that observed in $GATA1^{-}$ mice. In addition, $FOG\text{-}1^{-/-}$ mice have complete failure of megakaryocytopoiesis, establishing FOG-1 as the first identified transcription-associated factor selectively required to generate the entire megakaryocyte lineage. FOG-1's role in megakaryocyte and erythroid development requires direct physical interaction with GATA factors. The discrepancy between the relatively late block in megakaryocyte development seen in GATA1-deficient animals and the complete loss of megakaryocytopoiesis in $FOG\text{-}1^{-/-}$ mice is explained by overlapping FOG-dependent roles of GATA1 and GATA2 during early stages of megakaryocytopoiesis.

X-Linked Dyserythropoietic Anemia and Thrombocytopenia Due to GATA1 Mutations

Germline GATA1 mutations that impair binding to FOG-1 and/or DNA have been identified in several families with X-linked macrothrombocytopenia and/or anemia (GATA1 is located on the X chromosome in both humans and mice). The first case, reported by Weiss and colleagues, involved a woman with mild chronic thrombocytopenia who had two pregnancies with male offspring that were both complicated by severe fetal anemia and thrombocytopenia requiring in utero transfusions. Bone marrow examination after birth revealed

Inherited Causes of Thrombocytopenia

Although the most common cause of thrombocytopenia is immune thrombocytopenic purpura (ITP), it is important to maintain a high index of clinical suspicion for inherited disorders of thrombocytopoiesis. This is a particular problem because ITP is essentially a diagnosis of exclusion, and many inherited disorders mimic the macrothrombocytopenia seen in ITP. Making the correct diagnosis early is paramount, since it may spare patients unnecessary treatment with corticosteroids, other immunosuppressants, and/or splenectomy. In addition, it may be important in guiding decisions about surveillance for myelodysplasia or leukemia, screening for additional associated clinical problems, and/or possible family planning. Obtaining a careful family history, and sometimes obtaining blood counts on first-degree relatives, is important in fully evaluating patients with chronic thrombocytopenia. Associated abnormalities may provide important clues to the presence of a nonimmune familial thrombocytopenia. For instance, associated erythroid abnormalities and/or an X-linked inheritance pattern (GATA1 mutations) (obligate female carriers may have dimorphic populations of platelets); leukocyte Döhle bodies, +/– nephritis and sensineural hearing loss (Myh9 mutations); family history of myelodysplasia or myeloid leukemia (RUNX1 mutations); developmental delay, congenital cardiac anomalies, hand/face dysmorphogenesis (Paris-Trousseau/Jacobsen syndrome; Fli-1 [ETS-1] mutations); bleeding diathesis out of proportion to degree of thrombocytopenia (Bernard-Soulier syndrome). Mutations in the 5-UTR of the ANKRD26 gene have been described in a large number of families with autosomal dominant macrothrombocytopenia. A superb review of inherited thrombocytopenias and an excellent diagnostic algorithm has been provided by Savoia and colleagues.[29]

marked dyserythropoiesis and an overabundance of immature-appearing, dysplastic megakaryocytes that share many of the features of GATA1^{low} murine megakaryocytes. Remarkably, sequencing of the GATA1 gene from affected family members identified substitution of valine by methionine at codon 205 within the amino zinc finger. This mutation (GATA1^{V205M}) significantly impairs FOG-1 binding, but retains normal DNA affinity based on electromobility shift assays using synthetic oligonucleotides. This is consistent with the location of this residue on the surface of the zinc finger opposite the DNA binding face.

Several other GATA1 mutations have been linked to cases of familial X-linked macrothrombocytopenia with or without anemia (Table 26-1). These substitutions all impair FOG-1 binding, although to different degrees. Substitution of glycine by serine at codon 208 (GATA1^{G208S}) results in moderate to severe thrombocytopenia and mild dyserythropoiesis, but no anemia. Substitution of the same residue by arginine (GATA1^{G208R}) results in thrombocytopenia with anemia and severe dyserythropoiesis. Similarly, substitution of aspartic acid by glycine at codon 218 (GATA1^{D218G}) leads only to thrombocytopenia, whereas substitution of this same codon by tyrosine (GATA1^{D218Y}) leads to severe thrombocytopenia, moderate anemia, and marked dyserythropoiesis. The severity of the phenotype appears to correlate with the degree of FOG-1 binding impairment, suggesting that megakaryocytic development is more sensitive to affinity changes in GATA1: FOG-1 interactions than is erythroid development.

X-Linked Thrombocytopenia and β-Thalassemia Due to GATA1 Mutations

Mutations mapping to the DNA binding surface of the amino zinc finger of GATA1 have also been described (GATA1^{R216Q}). As expected, this reduces DNA affinity to double (palindromic) GATA sites but not to single GATA sites. FOG-1 binding is not substantially altered. Affected family members exhibit an X-linked β-thalassemia syndrome characterized by imbalance of alpha and beta globin chain synthesis, reticulocytosis and hemolysis. They also have mild to moderate thrombocytopenia. In vitro platelet aggregation studies are normal, but there is a prolonged bleeding time. Substitution of the same residue by tryptophan (R216W) produces thrombocytopenia, β-thalassemia intermedia, and congenital erythropoietic porphyria (CEP). The CEP is likely due to dysregulation of the GATA1 target gene uroporphyrinogen III synthase.

X-Linked Gray Platelet-Like Syndrome

Gray platelet syndrome (GPS) refers to a disorder of large platelets with absent or markedly reduced α-granules and/or α-granule proteins. Platelets from individuals with GATA1^{Arg261Gln} share some features with classical GPS. Ultrastructural studies of platelets from a different family with GATA1-related X-linked macrothrombocytopenia (GATA1^{G208S}) also demonstrate hypogranular platelets that contain small vacuoles, likely representing membranes of empty α-granules. However, the GATA1 mutant platelets also possess unique features such as masses of dense tubular system channels, dense double membranes, and platelets within platelets, not seen in classical GPS, suggesting a more general disorder of platelet biogenesis.

GATA1 Mutations in Down Syndrome Transient Myeloproliferative Disorders and Acute Megakaryoblastic Leukemia

About 10% of children with Down syndrome (DS; trisomy 21) are born with a transient myeloproliferative disorder (TMD), which is

Table 26-1 Reported GATA1 Mutations in Hematologic Disease With Associated Clinical and Biochemical Features

Mutation	Thrombo-cytopenia	Platelet Features	Anemia	Erythroid Features	Other Features	FOG-1 Binding	DNA Binding
V205M	Severe	Large*	Severe; fetal hydrops	Dyserythropoiesis	Cryptorchidism	Markedly reduced	Normal
G208S	Moderate	Large; decreased platelet aggregation	None			Moderately reduced	Normal
G208R	Severe	Large*	Moderate	Dyserythropoiesis	Cryptorchidism†	Not studied	Not studied
D218G	Moderate	Large; decreased platelet aggregation	None	Dyserythropoiesis		Moderately reduced	Normal
D218Y	Severe	Large*	Severe		Platelets in carrier female expressed only WT allele	Markedly reduced	Normal
R216Q	Moderate	Large; normal platelet aggregation in vitro, but prolonged bleeding time; grey platelet syndrome	Mild	Mild β-thalassemia	Splenomegaly	Normal	Decreased
R216W	Moderate	*	Mild	Mild β-thalassemia	Congenital erythropoietic anemia	Not studied	Not studied
G332C‡	None	Decreased platelet aggregation; dysplastic megakaryocytes	Variable	Macrocytosis	Neutropenia	Not studied	Not studied

‡Germline splice mutation results in exclusive production of the amino truncated GATA1s molecule.

characterized by an abundance of circulating erythromegakaryocytic precursor cells, pancytopenia, and in some cases, severe liver fibrosis. Remarkably, this myeloproliferation resolves spontaneously over the first few months of life. In about 20% to 30% of cases, Down syndrome–associated acute megakaryocytic leukemia (DS-AMKL) develops within a few years, sometimes preceded by a myelodysplastic phase. In 2002, Crispino and colleagues reported that DS-AMKL cells harbor acquired mutations in their GATA1 gene. Since then, several groups have reproduced these findings and identified similar mutations in DS-TMD cells.[25] Although a wide spectrum of mutations have been found, including missense, deletion, insertion, and splice-site mutations, they all involve exon 2 and result in the same outcome: generation of an amino terminal truncated protein (loss of amino acids 1-83) due to translation initiation from a downstream ATG codon (Fig. 26-10). This removes a region that functions as a transcriptional activation domain in transient transfection reporter assays. The mutations are detectable in bone marrow from DS-AMKL patients but disappear when patients enter remission, indicating a strong correlation between the mutated clone and the leukemic phenotype. Mutations involving exon 2 of GATA1 are highly specific for DS-AMKL and DS-TMD, or AMKL with acquired trisomy 21. There is only one reported case of such a mutation in AMKL without trisomy 21, and no mutations have been detected in DS-acute lymphoblastic leukemia or a large number of healthy individuals.

Analysis of stored neonatal blood spots shows the coexistence of several different GATA1 mutations (all resulting in the generation of GATA1s) in patients who subsequently developed DS-AMKL, suggesting an oligoclonal expansion. In a few cases in which material was available, identical GATA1 mutations have been found in both the DS-TMD and DS-AMKL cells from the same patient. DS-AMKL cells often harbor additional genetic abnormalities, such as trisomy 8 or tetrasomy 21, not observed in DS-TMD cells. Taken together, these findings support a clonal evolution model of DS-AMKL, with GATA1 mutations associated with an early initiating event.

Generation of knock-in mice that recapitulate the truncating GATA1 mutations show unexpected stage-specific effects on megakaryocytopoiesis. During fetal liver hematopoiesis, the mutant megakaryocytes markedly hyperproliferate, similar to what is observed for GATA1-deficient megakaryocytes. However, during adult-stage bone marrow hematopoiesis, megakaryocytopoiesis and thrombocytopoiesis appear normal. This suggests that the fetal liver and bone marrow cellular contexts interact differentially with the GATA1 truncated molecule. This may also explain the restriction of TMD to the neonatal period. A family has been described with members containing a germline GATA1 gene splice site mutation (G332C) that results in exclusive production of the GATA1s protein product. Affected individuals exhibit a unique phenotype characterized by trilineage bone marrow dysplasia, macrocytic anemia, and neutropenia. None of the family members has developed leukemia, suggesting that trisomy 21 plays a role in DS-TMD progression to DS-AMKL.

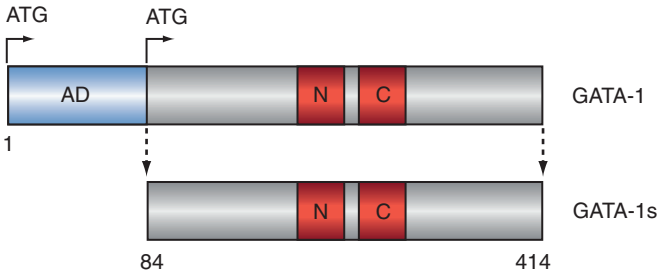

Figure 26-10 GENERATION OF AN AMINO TERMINAL TRUNCATED ISOFORM OF GATA1 BY MUTATIONS ASSOCIATED WITH DS-TMD AND DS-AMKL. Schematic representation of full-length GATA1 is shown on top; the truncated form (GATA1s), on bottom. The amino terminal transcriptional activation domain, as defined by reporter assays in transiently transfected cells, is indicated *(AD)*. The amino *(N)* and carboxyl *(C)* zinc fingers are shown as *gray boxes*. In DS-TMD and DS-AMKL, mutations involving exon 2 of GATA1 (point mutations, deletions, insertions, and/or splice site mutations) lead to exclusive translation from a downstream in-frame methionine at codon 84, producing the amino terminal truncated GATA1 protein (GATA1s).

Of note, Santoro and his colleagues previously reported that GATA1s is produced naturally at low levels in erythroid cells. They proposed that this might serve a regulatory role during normal hematopoiesis by acting as a dominant negative molecule at specific times/environmental stimuli. Endogenous GATA1s has also been detected in normal mouse fetal liver megakaryocytes and adult human bone marrow megakaryocytes. Thus it has been proposed that the ratio of GATA1 to GATA1s plays a role in developmental aspects of megakaryocytopoiesis and that acquired GATA1 mutations observed in DS-TMD and DS-AMKL, or germline mutations in the family described earlier, perturb hematopoiesis by altering this ratio.

ETS Family Transcription Factors

A common feature of megakaryocyte-specific genes is the presence of tandem binding sites for GATA and ETS transcription factors in their promoters and enhancers. The ETS transcription factor family is composed of a diverse group of proteins that share a common ETS DNA-binding domain, which recognizes a GGAA core sequence. Over 30 different ETS factors have been identified, at least nine of which (ELF1, ELF2, Fli-1, PU.1, TEL, GABPα, ETS1, ETS2, ELK4) are expressed in megakaryocytes. Functional studies have implicated several of these, including Fli-1, ETS1, TEL, and GABPα, in megakaryocytopoiesis.

Fli-1

The role of Fli-1 megakaryocytopoiesis is the best characterized of the ETS factors in terms of its functional role in megakaryocyte development. Fli-$1^{-/-}$ mice die during embryogenesis from hemorrhage, likely due to both vascular defects and dysmegakaryocytopoiesis. Colony assays show an increased number of megakaryocyte progenitors in Fli-$1^{-/-}$ embryos as compared with wild-type mice. However, the megakaryocytes from these colonies are small, contain a high nuclear/cytoplasm ratio, and have hypolobulated nuclei, disorganized platelet demarcation membranes, and reduced number of α-granules. Expression of the late megakaryocyte marker gene GPIX is markedly reduced, whereas expression of the early genes, TPO receptor, and αIIb are normal or mildly reduced, consistent with a role of Fli-1 in late megakaryocyte maturation. Fli-1 is involved in the synergistic transcriptional activation of several megakaryocyte-specific genes by GATA1 and FOG-1. Work by Poncz and colleagues shows that different ETS factors act in a stage-specific manner during megakaryocytopoiesis, with GABPα predominantly regulating genes active during early stages of megakaryocytopoiesis and Fli-1 during later stages.

Fli-1 has been implicated in the lineage commitment of bipotent erythroid-megakaryocyte progenitor cells to the megakaryocyte pathway. Fli-1 expression is downregulated as bipotent cells commit to the erythroid lineage, and its overexpression in the bipotent human erythroleukemia cell line K562 enhances the expression of several megakaryocyte-specific genes and induces a megakaryocyte phenotype. In addition, functional cross-antagonism occurs between Fli-1 and the erythroid-specific transcription factor EKLF.

Paris-Trousseau syndrome (OMIM 188925) and Jacobsen syndrome (OMIM 147791) are overlapping contiguous gene-deletion disorders in humans involving the long arm of chromosome 11 (11q23). The constellation of findings in these syndromes includes severe congenital cardiac abnormalities, trigonocephaly, mental retardation, dysmorphogenesis of the hands and face, and

macrothrombocytopenia. The etiology of the thrombocytopenia in these patients appears to be related to impaired platelet production, since platelet survival time is normal. Examination of bone marrow reveals significant dysmegakaryocytopoiesis with an abundance of micromegakaryocytes and death of large numbers of megakaryocytes during terminal stages of maturation. Peripheral blood platelets contain giant α-granules, which are thought to arise from aberrant α-granule fusion during prolonged residence in the bone marrow. The minimal chromosome regions deleted in Paris-Trousseau and Jacobsen syndromes associated with thrombocytopenia includes the genes for the ETS factors Fli-1 and ETS-1. Lentiviral expression of Fli-1 in $CD34^+$ cells from patients with Paris-Trousseau thrombocytopenia rescues megakaryocyte differentiation in vitro, providing strong evidence that it is deficiency of Fli-1 that is the cause of impaired thrombopoiesis in these patients. Of interest, Favier and colleagues have shown that in normal individuals, expression of Fli-1 is mostly monoallelic in early megakaryocytic progenitors ($CD41^+$/$CD42^-$ cells) but predominantly biallelic in later stages. They propose that the different populations of megakaryocytes seen in patients with Paris-Trousseau disorder arise from expression of the normal allele in the normally differentiating megakaryocytes, and the deleted allele (leading to complete loss of Fli-1 expression) in the dying population of megakaryocytes.

TEL (ETV6)

Generation of a fusion protein between TEL (ETV6) and RUNX1 is the most frequent chromosome translocation in childhood pre–B cell acute lymphoblastic leukemia. Although TEL is required for the ontogeny of all definitive hematopoiesis, a recent conditional knockout study of the TEL gene in mice demonstrates its specific requirement for adult-stage megakaryocytopoiesis.

RUNX1

In 1999, Gilliland and colleagues used positional cloning to identify the genetic cause of a rare dominant disorder characterized by thrombocytopenia, an aspirin-like functional platelet defect, and increased risk for developing acute myelogenous leukemia (FPD/AML; OMIM 601399).[26] They identified nonsense mutations, intragenic deletions, or missense mutations on one allele of the gene for RUNX1 (formerly called *AML-1* and *CBFA2*) that co-segregated with the disease in six separate pedigrees. These mutations all resulted in loss of function, indicating that haploinsufficiency of RUNX1 plays a causal role in this disorder. Bone marrow or peripheral blood from these patients were characterized by reduced megakaryocyte colony formation, indicating that RUNX1 dosage affects megakaryocytopoiesis.

RUNX1 is a member of an evolutionarily conserved family of transcription factors that share a conserved 128 amino acid domain in their amino half with homology to Drosophila *runt* gene. This region mediates binding to DNA (consensus [C/T]G[C/T]GGT), as well as to its heterodimeric binding partner CBF-β via protein-protein interactions. RUNX1 is the most frequently mutated transcription factors in human leukemia. In addition, acquired mutations in RUNX1 have been identified in significant number of patients with myelodysplastic syndrome (MDS), particularly those that progress to AML. Homozygous knockout of either RUNX1 or CBF-β in mice is embryonic lethal due to a complete failure of definitive hematopoiesis. This is thought to arise from a defect in the ontogeny of hematopoietic stem cells in the AGM region. More recent studies using conditional knockout of RUNX1 in adult hematopoiesis demonstrate a specific role of RUNX1 in megakaryocytopoiesis. Bone marrow deletion of RUNX1 in adult mice results in up to ≈80% reduction in peripheral blood platelet numbers, although no bleeding diathesis. Bone marrow megakaryocytes are small, lack lobulated nuclei, have poorly developed demarcation membranes, and reduced polyploidization. These findings are reminiscent of the abnormal "micromegakaryocytes" seen in humans with myelodysplastic syndromes. Paradoxically, there is an increase in in vitro megakaryocyte colony plating efficiency, suggesting an expansion of early megakaryocyte progenitors. These effects are cell-autonomous. No defects are seen in the erythroid lineage. Reduced dosage of RUNX1's essential cofactor CBF-β also perturbs megakaryocytopoiesis in vivo. Taken together, these findings indicate a specific role of RUNX1/CBF-β in megakaryocyte terminal maturation.

NF-E2 p45

NF-E2 is a heterodimeric transcription factor composed of two basic region-leucine zipper (bZip) subunits: a hematopoietic-specific 45 kDa protein (p45) and a widely expressed 18 kDa subunit (p18). NF-E2 p45 is expressed in erythroid, megakaryocytic and mast cell lineages. In vitro studies implicated NF-E2 p45 as a critical factor for β-globin expression. Unexpectedly, NF-E2 $p45^{-/-}$ mice were found to have only mild perturbations of the erythroid lineage. However, these mice fail to produce platelets secondary to a maturational arrest in the megakaryocyte lineage, and succumb to hemorrhage in the neonatal period. Since the initial studies, NF-E2 p45 has been recognized as being a major regulator of terminal megakaryocyte maturation and platelet release. Notably, although NF-E2 $p45^{-/-}$ mice are severely thrombocytopenic, they have normal serum levels of TPO. In addition, megakaryocytes from these animals proliferate in vivo in response to TPO administration. These findings suggest that NF-E2 p45 regulates target genes independent of the action of TPO.

Several important target genes of NF-E2 p45 have been identified, including β-1 tubulin, 3β-hydroxysteroid dehydrogenase (3β-HSD), thromboxane synthase, caspase 12, and Rab27b. β-1 tubulin is a megakaryocyte-restricted isoform of β-tubulin that plays a key role in the marginal band structure of platelets and is essential for their discoid shape. Deficiency of β-1 tubulin leads to spherocytic platelets. Heterozygosity for a polymorphism (Q43P, due to the double nucleotide substitution AG>CC) in the human β1-tubulin gene is present in about 11% of individuals in a Caucasian northern European population and correlates with a reduced risk for cardiovascular disease in man. This may be due to alterations in platelet structure and function. 3β-HSD catalyzes autocrine biosynthesis of estradiol within megakaryocytes and plays an important role in proplatelet formation.

p18 (also called mafK) is a member of a family of small maf proteins (mafF, mafG, mafK) related to the chicken v-maf oncoprotein. Knockout of mafK, and the related mafF, in mice has no discernable phenotypes, whereas deficiency of mafG leads to mild thrombocytopenia. Compound mafK::mafG null mice have profound thrombocytopenia, phenocopying NF-E2 p45 mice. This indicates functional redundancy of the small maf family members in megakaryocytopoiesis.

SCL (TAL1)

SCL (also known as *TAL1*) is a member of the basic helix-loop-helix member of transcription factors and is expressed predominantly in megakaryocytic and erythroid cells. Dysregulated expression of SCL due to chromosomal translocation is associated with certain cases of T-cell acute lymphoblastic leukemia. SCL forms obligate heterodimers with ubiquitously expressed E proteins (such as E12 and E47), which bind to E-box motifs (sequence CANNTG). It participates in multiprotein complexes that include E2A, GATA1, LMO2, LDB1, and the repressor ETO-2. $SCL^{-/-}$ mice die during embryogenesis as a result of failure of all hematopoiesis and defective vasculogenesis. However, conditional SCL knock-out models show a specific role for SCL in late stages of megakaryopoiesis and stress thrombopoiesis during adult hematopoiesis. SCL-null megakaryocytes have disorganized demarcation membrane systems and a reduced number of platelet granules. SCL modulates thrombopoiesis, in part, by direct transcriptional activation of NF-E2 p45.

Other Transcription Factors

The transcription factors discussed thus far are those that have received the most in-depth study in terms of their roles in megakaryocytopoiesis. Additional factors involved in megakaryocytopoiesis and/or thrombopoiesis have been identified, although their roles are just beginning to be explored. Gfi-1b (*Gfi* standing for "growth factor independent") is a member of a family of hematopoietic expressed zinc finger transcription factor proto-oncogenes that contain a unique amino terminal transcriptional repressor SNAG domain. Knockout of Gfi-1b in mice results in embryonic lethality due to severe anemia. The fetal liver of mutant mice contains erythroid and megakaryocytic progenitors that are blocked in their maturation. Culture of these cells in the presence of thrombopoietin, in contrast to those from wild-type animals, generates only small colonies and the cells are acetylcholinesterase negative (a marker of maturing megakaryocytes in mice). They contain markedly reduced mRNA transcript levels of vWF, NF-E2 p45, c-Mpl, and GPIIb, compared with wild-type, suggesting a requirement for Gfi-1b in at least relatively early stages of megakaryocytopoiesis. Gfi-1 has been shown to repress target genes by recruitment of histone lysine methyltransferases.

Warren and colleagues performed an ENU mutagenesis screen in TPO receptor$^{-/-}$ mice in order to identify factors that might influence thrombocytopoiesis. They identified two independent loss-of-function alleles of the transcription factor c-Myb (substitution of valine for aspartic acid at residue 152 within the DNA binding domain and residue 384 within the leucine zipper domain). Both TPO receptor$^{-/-}$ and wild-type mice containing these mutations have supraphysiologic production of platelets as a result of excessive megakaryocytopoiesis, at the expense of erythroid and lymphocyte development. Megakaryocytes from these animals have a 200-fold increased sensitivity to GM-CSF, suggesting dysregulation of signaling pathways. Similar megakaryocytic hyperplasia and thrombocytosis occur in mice containing germline c-Myb mutations that disrupt binding the transcriptional coactivator p300. Thus c-Myb may play an important negative regulatory function in megakaryocytopoiesis and thrombocytopoiesis.

Megakaryocyte Enhancesome Complex

A number of biochemical and genome-wide chromatin occupancy studies have provided evidence for physical and functional interactions between a core set of megakaryocyte transcription factors that includes GATA1, GATA2, Fli-1, RUNX1, and SCL/TAL1.[27] This suggests that a specific "enhancesome complex" involving these factors drives megakaryocyte-specific gene expression.

MICRORNAS IN MEGAKARYOCYTOPOIESIS

MicroRNAs (miRNAs) are a recently discovered class of small (typically 19-25 nucleotide) noncoding RNAs that interact in a sequence-specific manner with mRNAs (typically in their 3′ untranslated region in mammals) and modulate gene expression through either enhanced mRNA decay or inhibiting translation. There is increasing evidence that they play significant roles in development and differentiation, likely by fine-tuning tissue-specific transcription factor expression. Each miRNA can have multiple target genes, and conversely, each mRNA can be subject to regulation by multiple miRNA species. In addition, transcription of miRNAs is itself mediated by RNA polymerase II and subject to control by transcription factors. Therefore complex regulatory networks can exist between miRNAs and transcription factors. A number of miRNAs have been shown to influence thrombopoiesis.[28] miR-150 enhances megakaryocytopoiesis at the expense of erythropoiesis, suggesting a critical role in the cell fate decision of bipotent megakaryocyte-erythroid progenitor cells. This is mediated, at least in part, via targeting the 3′-UTR of c-MYB mRNA transcripts. Thrombopoietin signaling increases miR-150 levels. miR-155 inhibits megakaryocytopoiesis by targeting ETS1 and Meis1 transcription factors. Other miRNAs have been implicated in controlling thrombopoiesis, but the evidence supporting a functional role is not as strong as for miR-150 and miR-155. miRNAs are also present in platelets. Further studies are needed to examine their potential role in platelet activation and function.

FUTURE DIRECTIONS

Although the molecular details regarding the regulation and generation of platelets remain to be fully elucidated, considerable progress has been made over the past few decades. This has been significantly facilitated by the isolation of TPO and its receptor. Important models of thrombocytopoiesis have now been tested rigorously in vivo, yielding new insights into the final stages of platelet formation and shedding. These studies highlight the efficient mechanisms that have developed to satisfy the demands for dynamic and high-output platelet production. Several important transcription factors have been identified that regulate different stages of megakaryocytopoiesis, and mutations in these, and other genes, have been linked to human disorders of thrombocytopoiesis. The role of miRNAs in controlling thrombopoiesis is beginning to be appreciated. Although mouse models have played important roles in the analysis of these genes, it is becoming clear that they do not always faithfully recapitulate human disease. In addition, several studies have documented important differences between rodent and human platelets, including differences in size, circulating numbers, and DMS ultrastructural features. Thus some caution must be exercised when extrapolating results of mouse studies to human thrombocytopoiesis. The advent of megakaryocyte in vitro differentiation systems using human embryonic stem (ES) cells and/or CD34^{+} cells should provide important tools for future studies geared toward understanding and treating human disorders of megakaryocytopoiesis and thrombocytopoiesis.

CHAPTER 27

INHERITED FORMS OF BONE MARROW FAILURE

Yigal Dror and Melvin H. Freedman

Inherited bone marrow (BM) failure is defined herein as decreased production of one or more of the major hematopoietic lineages due to mutations that were derived from the parents or occurred de-novo (Table 27-1). Although outdated, the term "constitutional" has been used interchangeably with "inherited" and similarly implies that a genetic abnormality causes the BM dysfunction. The designation "congenital" has a looser connotation and refers to conditions that manifest early in life, often at birth, but does not imply a particular causation. Therefore, "congenital BM failure" is not necessarily inherited and may be caused by a de novo gene mutation during early embryogenesis or by acquired factors such as viruses, drugs, or environmental toxins.

Hematopoiesis is an orderly but complex interplay of stem and progenitor cells, growth factors, BM stromal elements, and positive and negative cellular and humoral regulators. Thus, BM failure can potentially occur at several critical points in the hematopoietic lineage pathways. With regard to inherited BM disorders, genetic mutations interfere with orderly hematopoiesis and cause the BM failure. The discovery of specific, high-penetrance mutant alleles associated with discrete inherited BM failure syndromes provides evidence for this. Many of these alleles are of genes that directly affect physiologic cell survival and function pathways that are essential for normal hematopoiesis (e.g., DNA repair, telomere maintenance, ribosome biogenesis, microtubule stabilization, chemotaxis, signaling from hematopoietic growth factors, signal transduction related to hematopoietic cell differentiation, and granulocytic enzymes). Modifying genes, epigenetic processes, acquired factors, and chance effects may also be operative and interact with the mutant genes to produce overt disease with varying clinical expression. Hence, the disorders listed in Table 27-1 can be transmitted in a simple Mendelian pattern determined primarily by mutant genes with inheritance patterns of autosomal dominant, autosomal recessive, or X-linked types. Alternatively, some or all of these can be multifactorial in origin caused by an interaction of multiple genes and a variety of exogenous or environmental determinants.

The incidence of the inherited BM failure syndromes (IBMFSs) can be approximated from experience at large centers. Data from Children's Hospital Boston show that the inherited syndromes comprise about 30% of cases of pediatric BM failure with Fanconi anemia (FA) cases leading the list. Data from the Canadian Inherited Marrow Failure Registry (CIMFR) suggest an incidence of about 65 cases diagnosed per million live births per year. Importantly, none of these syndromes is restricted to the pediatric age group. Patients with dyskeratosis congenita (DC) and FA may be detected for the first time in adulthood. Similarly, cases of Shwachman-Diamond syndrome (SDS), Diamond-Blackfan anemia (DBA), and Kostmann (KS) (congenital) neutropenia may first become evident in young adults.

BI-LINEAGE AND TRI-LINEAGE CYTOPENIAS

Fanconi Anemia

Background

Fanconi anemia is inherited in an autosomal recessive manner in 98% of cases. In about 2% of cases, it is transmitted in an X-linked recessive mode caused by a mutant *FA type B* gene.

Although the original report of FA in 1927 by Dr. Guido Fanconi described pancytopenia combined with physical anomalies in three brothers, a published summary in 2010 of more than 2000 FA cases has underscored the clinical variability of the condition. Basically, FA is a *genomic instability disorder* characterized by chromosomal fragility and breakage, a defect in DNA repair, progressive BM cellular underproduction, peripheral blood cytopenias, developmental anomalies, and a strong propensity for hematologic and solid tumor cancers.

There are four possible clinical presentations: FA patients may have (1) typical physical anomalies but normal hematology; (2) normal physical features but abnormal hematology; (3) normal physical features *and* normal hematology; or (4) physical anomalies and abnormal hematology, the so-called classic phenotype that fits the original description (Fig. 27-1). There can also be sibling heterogeneity in presentation with discordance in clinical and hematologic findings, even in affected monozygotic twins. FA patients show abnormal chromosome fragility that is readily seen in metaphase preparations of peripheral blood lymphocytes cultured with phytohemagglutinin (PHA) and enhanced by adding a DNA interstrand cross-linking agent, either mitomycin C (MMC) or diepoxybutane (DEB) (see Abnormal Chromosome Fragility section later). Using published information, the median age at diagnosis of FA is about 6.5 years with a reported range from birth to 49 years.

Epidemiology

The overall prevalence of FA is 1 to 5 cases per million with a carrier frequency of one in 200 to 300 in most populations. Data from the CIMFR showed a prevalence of 11.4 cases per million live births per year. It occurs in all racial and ethnic groups. Spanish Gypsies have the world's highest prevalence of FA with a carrier frequency of one in 64 to one in 70 for a common founder mutation. A founder effect has also been demonstrated in Afrikaners in South Africa in whom one specific mutation is common (frequency, one in 83), as well as in Ashkenazi Jews (one in 89), Moroccan Jews, Tunisians, sub-Saharan African blacks, Indian, Israeli Arabs, Brazilians, and Japanese.

Etiology and Genetics

Complementation Subtyping

A breakthrough in the search for FA genes evolved from the important observation that fusion of normal cells with FA cells (i.e., cell hybridization) resulted in correction of MMC hypersensitivity of the FA cells in a growth inhibition assay. Thus, the cell hybridization corrected the abnormal FA chromosome fragility, a process known as *complementation*. It was further demonstrated that cell hybridization in several unrelated FA patients could also produce the corrective effect on chromosomal fragility by complementation, which led directly to subtyping of patients into discrete complementation groups. A second method for complementation testing, which is currently used more often for research and clinical purposes, is retroviral transduction. The cDNA of each wild-type FA gene can be transfected into T cells from a newly diagnosed patient using retroviral

AD, Autosomal dominant; *AR,* autosomal recessive; *IBMFSs, inherited* bone marrow failure syndromes; *UK,* unknown; *WHIM,* warts, hypogammaglobulinemia, infections, and myelokathexis; *X-L,* X-linked recessive.

Figure 27-1 CLASSIC PHENOTYPE OF FANCONI ANEMIA. The patient has pigmentary changes around the neck, shoulders, and trunk; short stature; absent radii and absent thumbs bilaterally; microcephaly; and low-set ears.

vectors. If a specific wild-type FA gene corrects (complements) the abnormal chromosome breakage in the patient's T cells in culture on exposure to DEB, the mutant gene is identified. At least 15 complementation groups (termed types A, B, C, D1/BRCA2, D2, E, F, G, I, J, L, M, N, O, and P) have been distinguished on the basis of somatic cell hybridization or retroviral transduction experiments.

Fanconi Anemia Genes

The identification of the 15 subtypes facilitated the cloning of the 15 corresponding FA or *FANC* genes by 2011 (see Table 27-1). The first gene, *FANCC* on chromosome 9q22.3, was discovered in 1992 in Toronto, and then the other genes, corresponding to each of the other complementation groups, were subsequently cloned: *FANCA* on 16q24.3, *FANCB* on Xp22.31, *FANCD1/BRCA2*

on 13q12.3, *FANCD2* on 3p25.3, *FANCE* on 6p21.3, *FANCF* on 11p15, *FANCG* on 9p13, *FANCI* on 15q26.1, *FANCJ/BACH1/BRIP1* on 17q22, *FANCL* on 2p16.1, *FANCM* on 14q21.3, *FANCN/PALB2* on 16p12, *FANCO/RAD51C* on 17q22, and *FANCP/SLX4* on 16p13.3.

Of patients tested, up to 70% have mutant *FANCA*, 14% *FANCC*, 10% *FANCG*, 3% *FANCD1*, 3% *FANCD2*, 3% *FANCE*, and 2% or less for the others. FA complementation groups can now be accurately determined clinically by identifying which cDNA of the 15 FA-related genes, when expressed in cells from a newly diagnosed FA patient, corrects the MMC hypersensitivity phenotype.

Murine Models

There are at least 7 FA mouse models, each resulting from targeted disruption of one of the following: FancA, FancC, FancG, FancN, FancD1, FancD2, and the Usp1 gene that encodes the enzyme that deubiquitinates FANCD2. With the exception of FancC and FancG mice, not all other knock-out mouse models recapitulate the hypocellularity and cytopenia that characterizes FA. However, these models provide insight into the various functions of the genes and the role of individual FA mutations. Consistent findings in some or all of the mice include impaired proliferation of BM hematopoietic progenitors, hypogonadism, impaired fertility, growth retardation, microphthalmia, development of cancers, hypersensitivity of BM progenitor cells to administered MMC, as well as to interferon-γ (INF-γ) or tumor necrosis factor-α (TNF-α) in vitro and in vivo. The phenotype of these mutant mice shows abnormal G_2/M progression of the cell cycle similar to FA patients.

Function of FANC Proteins

Cells and cell lines from FA patients are phenotypically similar regardless of the complementation group that they represent. A hypothesis was therefore formulated and subsequently substantiated that the 15 wild-type FANC proteins function in a common response pathway to repair DNA damage incurred during DNA replication.

There are three discrete steps in the FA DNA damage response pathway: (1) ***Core complex***. Eight wild-type FANC proteins (FANCA, FANCB, FANCC, FANCE, FANCF, FANCG, FANCL, and FANCM) and four additional proteins (FAAP16, FAAP 20, FAAP24, and FAAP100) form a single large nuclear protein *"core complex"* as the first step. The *core complex* functions as an ubiquitin ligase of which FANCL is the catalytic subunit. (2) ***ID complex***. The activated *core complex* results in conversion of two downstream protein targets, FANCI and FANCD2 (called the *"ID complex"*), from unubiquitinated isoforms to monoubiquitinated isoforms. Monoubiquitination does not occur if the *core complex* upstream of the *ID complex* is not intact or if FANCL is mutated, and therefore FA cells from patients with upstream mutations do not show the monoubiquitinated FANCI/FANCD2. (3) ***Downstream effector complexes***. In normal cells after monoubiquitination of the *ID complex,* the wild-type *core complex* translocates the monoubiquitinated *ID complex* to chromatin and localizes the *ID complex* to nuclear foci, where it forms downstream effector complexes with five other FANC genes *FANCD1/BRCA2, FANCJ/BACH1/BRIP1, FANCN/PALB2, FANCO/Rad51C,* and *FANCP/SLX4*), as well as with DNA-repair proteins such as BRCA1, RAD51, MRE11-RAD50-NBS1, replication protein A, PCNA, and *BLM* to complete the final step of the DNA repair response.

There are important protein–protein interactions between FA proteins and non-FA "binding partners" for cell survival. FANCC and FANCD2 form complexes with members of the signal transducer and activator of transcription (STAT) family of transcription factors in cytokine-mediated biologic responses. Secondly, heat shock proteins provide several cell survival functions, and FANCC protein specifically facilitates the anti-apoptotic role of Hsp 70. FANCC also interacts with cdc2, PKR, and p53, suggesting that FANCC has other roles that are independent of DNA damage recognition and repair. Finally, GSTP1 is an enzyme that detoxifies byproducts of redox stress and xenobiotics and *FANCC* protein enhances GSTP1 activity in cells exposed to apoptosis inducers.

Genotype–Phenotype Correlations

The clinical severity of FA is partly determined by the specific *FANC* gene involved and by the type of mutation. ***FANCA*** patients who are homozygous for null mutations and produce no protein tend to have an earlier onset of anemia and a higher propensity to leukemic transformation compared with hypomorphic *FANCA* patients who produce protein, albeit abnormal. Compared with other ***FANCC*** mutations, *FANCC* IVS4+4A>T, commonly found in Ashkenazi Jews, is particularly severe and linked with early-onset anemia; early BM failure; and severe physical anomalies, including some cases with physical features of VACTERL-H syndrome (a well-known malformation association, including vertebral, anal, tracheoesophageal, renal, and limb abnormalities). Of genetic-ethnic interest, the identical IVS4+4A>T mutation in Japanese FA patients manifests with a *milder* phenotype than in Ashkenazi Jews. ***FANCD1/BRCA2*** and ***FANCN/PALB2*** mutations are both associated with a significant predisposition to develop acute myeloid leukemia (AML) and with a severe physical anomaly phenotype. The VACTERL-H cluster of anomalies is closely linked with biallelic mutations of *FANCD1/BRCA2*. Null mutations of ***FANCG*** correlate with very severe manifestations compared with most other *FANC* mutations and correlate with early-onset anemia and BM failure, a higher incidence of AML, and severe physical anomalies. ***FANCD2*** and ***FANCI*** mutations also correlate with severe anomalies, and *FANCI* is associated with early-onset anemia.

Pathophysiology

Wild-type FA proteins are part of a cluster of survival signaling molecules that protect against genotoxic insult and suppress apoptosis signaling. With inactivation of any of the 15 known FA genes, the prosurvival benefit is lost. This underlies the phenotype of clinical FA but does not explain or unify the relationship between congenital anomalies, BM failure, the predisposition to cancer, and chromosome fragility.

Two theories of the pathophysiology of FA relate to either (1) a heightened sensitivity to oxygen, resulting in cell damage; or (2) defective DNA repair. The oxygen sensitivity phenotype of FA cells is characterized by overproduction of oxygen radicals, a deficient oxygen radical defense, a deficiency in superoxide dismutase, and poor cell growth at ambient oxygen, all producing shortened cell survival. A cardinal phenotype of FA cells is an abnormality in cell cycle distribution with an increased number of cells with 4N DNA content arising from a delay in the G_2/M or late S phase of the cell cycle. The strongest evidence supporting an oxygen metabolism deficiency in FA is a *reduction* of FA cells with 4N DNA content when grown at *low* oxygen levels and the unexpected appearance of 4N DNA content when normal cells are grown at *high* oxygen levels. Of note, some wild-type FA proteins play a role in redox-related functions. FANCC associates with NADPH (nicotinamide adenine dinucleotide phosphate), cytochrome P-450 reductase, and glutathione S-transferase, proteins with redox functions. FANCA and FANCG are redox-sensitive proteins that multimerize after H_2O_2 treatment, prompting the notion that the FA pathway may function in oxidative stress management.

The best evidence supporting the theory that the primary defect is in DNA repair relates to the critical role of wild-type FANC proteins in the DNA damage response pathway. Whereas clastogenic bifunctional cross-linker agents such as MMC and DEB induce chromosomal breakage in FA cells, monofunctional chemical agents do not, indicating that FA cells cannot repair interstrand cross-links. There were also experiments in the 1980s in which the frequency of mutations induced by 8-methoxypsoralen plus near-ultraviolet radiation at the *HPRT* locus was lower in FA cells than in control

participants. These results indicated that FA cells cannot repair cross-links through the normal pathway involving mismatch repair, recombinational repair after bypass of the lesion, or both. Additional evidence for defective DNA repair in FA cells includes an accumulation of DNA adducts, a failure to arrest DNA synthesis in response to DNA damage, increased homologous recombination, defective nonhomologous end joining, abnormal induction of p53, and increased apoptosis.

The two theories for the pathophysiology of FA can be reconciled theoretically. We speculate that biallelic gene inactivation in autosomal recessive FA and monoallelic gene inactivation in X-linked recessive FA could either make the repair pathway sensitive to oxidative damage or cause a transient increase of oxidative damage to which the repair machinery is particularly sensitive.

Hematopoietic Dysfunction

Hematologic abnormalities in FA are evident at the hematopoietic progenitor cell level in BM and peripheral blood. The frequencies of CFU-E (colony-forming unit-erythroid), BFU-E (burst-forming unit-erythroid), and CFU-GM (colony-forming unit-granulocyte macrophage) colony-forming cells are reduced fairly consistently in almost all patients after aplastic anemia ensues as well as in a few patients before the onset of aplastic anemia. Although FA BM cells show normal transcripts for the α and β chains of the GM-CSF (granulocyte macrophage colony-stimulating factor)/interleukin-3 (IL-3) receptor and for c-kit protein, there is a deficient proliferative response of CFU-GEMM (colony-forming unit granulocyte, erythrocyte, macrophage, megakaryocyte), BFU-E, and CFU-GM progenitors in response to GM-CSF plus stem cell factor (SCF) (c-kit ligand) or to IL-3 plus SCF. Because all hematopoietic lineages are affected, the basic defect is presumed to be at the hematopoietic stem cell (HSC) level. Cure of FA BM failure by HSC transplantation (HSCT) supports this view. Confirmatory data for defective stem cells in FA using long-term BM cultures were reported by one group but not confirmed by another. Decreased colony numbers in these studies can be interpreted as the result of an absolute decrease in progenitors and/or progenitors that have faulty proliferative properties and cannot form colonies in vitro.

Additional factors are operative in FA BM failure. Telomeres, the non-encoding DNA at each end of chromosomes, shorten with each round of cell division in normal human somatic cells. Their length is a reflection of the mitotic history of the cell. Telomerase, a ribonucleoprotein reverse transcriptase that can restore telomere length, is variably present in hematopoietic progenitors. Leukocyte telomere length is significantly shortened in FA patients but there is increased telomerase activity, suggesting an abnormally high proliferative rate of progenitors which ultimately leads to their premature senescence. In parallel, increased BM cell apoptosis has been demonstrated in FA patients and in knock-out mouse models and is mediated by Fas, a membrane glycoprotein receptor containing an integral death domain. FA cells exposed to TNF-α, INF-γ, MIP-1α, Fas ligand, and double-stranded RNA undergo exaggerated apoptotic responses.

Studies of cytokines in FA patients have shown varied abnormalities. Although FA fibroblasts showed no deficiencies in SCF or M-CSF (macrophage colony-stimulating factor) production, variability ranging from diminished production to augmentation of production of IL-6, GM-CSF, and G-CSF (granulocyte colony-stimulating factor) has been observed in different patients. A consistent finding that may relate directly to pathogenesis is diminished IL-6 production in FA patients and markedly increased TNF-α generation.

Clinical Features

History and Physical Examination

Historically, the diagnosis of FA was based on signs and symptoms related to aplastic anemia and the presence of characteristic congenital physical anomalies. However, about 30% of FA patients may lack anomalies. The older historical terms *Estren-Dameshek aplastic anemia* and *constitutional aplastic anemia type II* referred to such patients. Confirmatory diagnostic chromosome testing data from the International Fanconi Anemia Registry (IFAR, Rockefeller University) showed that 39% of FA patients had aplastic anemia and anomalies, 30% had aplastic anemia but no anomalies, 24% had anomalies but not aplastic anemia, and 7% had neither. Hence, the Estren-Dameshek cases that lack anomalies should not be considered a separate entity but as part of the continuum of FA.

Table 27-2 lists the characteristic physical abnormalities and their approximate frequency based on more than 2000 published case reports. The two most common anomalies are *skin hyperpigmentation* and *short stature,* each with a frequency of 40% of cases. Characteristically, the hyperpigmentation is a generalized brown melanin-like splattering that is most prominent on the trunk, neck, and intertriginous areas and that becomes more obvious with age. Café-au-lait spots are common alone or in combination with the generalized hyperpigmentation and sometimes with vitiligo or hypopigmentation. The skin pigmentation should not be confused with hemosiderosis-induced bronzing in transfusion-dependent patients who have not been adequately iron chelated. In those with short stature (growth failure), most are less than the third percentile for height. In some patients, growth failure is associated with endocrine abnormalities. In one report, spontaneous overnight growth hormone secretion was abnormal in all patients tested, and 44% had a subnormal response to growth hormone stimulation. Approximately 40% of patients also have overt or compensated hypothyroidism, sometimes in combination with growth hormone deficiency.

Malformations involving the upper limbs are common, especially hypoplastic, supernumerary, bifid, or absent thumbs. Hypoplastic or absent radii are always associated with hypoplastic or absent thumbs in contrast to the thrombocytopenia with absent radii (TAR) syndrome in which thumbs are always present. Less often, anomalies of the feet are seen, including toe syndactyly, short toes, a supernumerary toe, clubfoot, and flat feet. Congenital hip dislocation and leg abnormalities are occasionally seen. Male patients often have gonadal and genital abnormalities, including an underdeveloped penis or micropenis, undescended, atrophic, or absent testes, hypospadias, phimosis, and an abnormal urethra. Female patients occasionally have malformations of the vagina, uterus, or ovary. Renal anomalies occur but require imaging for documentation. Ectopic, pelvic, or horseshoe kidneys are detected often, as are duplicated, hypoplastic, dysplastic, or absent organs. Occasionally, hydronephrosis or hydroureter is present.

Table 27-2 Characteristic Physical Anomalies in More Than 2000 Published Case Reports of Patients With Fanconi Anemia

Anomalies	Approximate Frequency (%)
Skin pigment changes or café-au-lait spots	40
Short stature	40
Upper limb anomalies (thumbs, hands, radii, ulnae)	35
Hypogonadal and genitalia changes (mostly male)	27
Other skeletal findings (head or face, neck, spine)	25
Eye, eyelid, or epicanthal fold anomalies	20
Renal malformations	20
Gastrointestinal or cardiopulmonary malformations	11
Ear anomalies (external and internal), deafness	10
Hips, legs, feet, toe abnormalities	5
CNS imaging anomalies	3

From Shimamura A, Alter BP: Pathophysiology and management of inherited bone marrow failure syndromes. *Blood Rev* 24:101, 2010.
CNS, Central nervous system.

Many patients have a *Fanconi facies,* and unrelated patients can resemble each other almost as closely as siblings. The head and facial changes vary but commonly consist of microcephaly; small eyes; epicanthal folds; and abnormal shape, size, or positioning of the ears (see Fig. 27-1). Anomalies in the tympanic membrane and middle ear ossicles are seen in almost 70% of patients, resulting in hearing loss in most affected patients. Approximately 10% of FA patients are cognitively impaired.

Laboratory Manifestations

Peripheral Blood and Bone Marrow Findings

A cardinal feature is the gradual onset of BM failure usually in the first decade of life, with declining values in one or more hematopoietic lineages. Of 754 FA patients followed prospectively by the IFAR, 80% had hematologic abnormalities other than acute leukemia or myelodysplastic syndrome (MDS). The cumulative incidence of BM failure by 40 years of age was 90%. Patients with *FANCC* mutations appeared to have the earliest onset of changes and the highest incidence (see Phenotype-Genotype Correlations section). Thrombocytopenia with red blood cell (RBC) macrocytosis usually develops initially, with subsequent onset of granulocytopenia and then anemia. Severe BM aplasia eventually ensues in most cases, but the degree of pancytopenia is variable and evolves over a period of months to years. The development of aplastic anemia can be accelerated by intercurrent infections or by drugs such as chloramphenicol. Within families, there is a tendency for the hematologic changes to occur at approximately the same age in affected siblings.

The RBCs are macrocytic with mean corpuscular volumes (MCVs) often above 100 fl even before the onset of significant anemia. Erythropoiesis is characterized by increased fetal hemoglobin (HbF) levels and increased expression of i antigen but not necessarily both features in individual cells. The increased HbF production is not clonal and has a heterogeneous distribution. Ferrokinetic studies indicate that most patients have an element of ineffective erythropoiesis. The RBC lifespan may be slightly shortened, but this is a minor contributory factor to the anemia.

In the early stages of the disease, the BM can show erythroid hyperplasia, sometimes with dyserythropoiesis, myelodysplastic changes, and even megaloblastic-appearing cells. Dysplastic changes may be very prominent with nuclear–cytoplasmic dyssynchrony, hypolobulated megakaryocytes, and binucleated erythroid cells; the findings are difficult to distinguish from MDS. As the disease progresses, the BM becomes hypocellular and fatty, sometimes in a patchy manner, and shows a relative increase in lymphocytes, plasma cells, reticulum cells, and mast cells. When full-blown BM failure occurs, the morphology of the BM biopsy is identical to severe acquired aplastic anemia.

Abnormal Chromosome Fragility. A major finding in FA is abnormal chromosome breakage seen in metaphase preparations of peripheral blood lymphocytes cultured with PHA. The karyotype is characterized by chromatid breaks, rearrangements, gaps, endoreduplications, and chromatid exchanges. Cultured skin fibroblasts also show the abnormal karyotype, underscoring the systemic nature of the disorder. The abnormal lymphocyte chromosome patterns and the number of breaks per cell have no direct correlation with the hematologic or clinical course of individual patients.

Although the breakage is increased in these baseline lymphocyte cultures, it is strikingly enhanced by adding a bifunctional DNA interstrand cross-linking agent, either DEB or MMC. This is the recommended diagnostic test for FA. Indeed, homozygous FA cells are hypersensitive to many oncogenic and mutagenic inducers such as ionizing radiation; SV40 viral transformation; and alkylating and chemical agents, including cyclophosphamide, nitrogen mustard, and platinum compounds, but DEB and MMC have supplanted them for diagnostic testing.

For a definitive diagnosis of FA, the IFAR has defined FA as being associated with increased numbers of chromosome breaks per cell occurring after exposure to DEB with a range of 1.06 to 23.9 compared with the normal control range of 0.00 to 0.10. Further supportive features are unusual chromosome abnormalities such as tri-radial and quadri-radial figures. This pattern of abnormal chromosome breakage can also be used to make a prenatal diagnosis of FA. Diagnostic testing can be performed on fetal amniotic fluid cells obtained at week 16 of gestation or on chorionic villus biopsy specimens at 9 to 12 weeks of gestation. A very high degree of prenatal diagnostic accuracy has been obtained by looking at both spontaneous and DEB-induced breaks in fetal tissue. DEB testing of heterozygote carriers is unreliable for diagnosis because there is overlap of results with normal individuals.

A scoring system was developed for the probability of an accurate diagnosis of FA using discriminating clinical and laboratory variables in patients enrolled in the IFAR whose diagnosis was confirmed by DEB-induced chromosomal breakage analysis. The scoring system was useful in proving that DEB-induced chromosomal breakage results could be correlated with common FA findings. DEB testing is considered by the IFAR to be the gold standard for diagnosis, but MMC testing is still used in many laboratories.

DEB and MMC also induce cell cycle arrest in G2/M in cultures of FA lymphocytes or fibroblasts leading to a resultant 4N DNA cellular content. This alteration can be detected by flow cytometry and has been used to diagnose FA. It requires sophisticated instrumentation and is not used as widely as the DEB or MMC chromosome breakage assay.

Somatic Mosaicism. About 10% to 15% of patients with clinical FA do not show increased chromosome breakage when tested with DEB or MMC. These patients usually have hematopoietic cell somatic mosaicism as a result of a molecular genetic correction in a stem cell, resulting in one normal allele. The mechanisms for this phenomenon include gene conversion events, back mutations, or compensatory deletions or insertions. The end result is mixed populations of somatic cells, some with two abnormal alleles and some with one. If FA is strongly suspected, a skin biopsy is performed to assess chromosomal breakage in cultured fibroblasts with DEB or MMC rather than in lymphocyte cultures.

Immunoblotting for FANCD2. An accurate diagnostic and subtyping assay for FA has been introduced in research laboratories. Primary lymphocytes or fibroblasts are assayed for FANCD2 after exposure to MMC or radiation by immunoblotting, which distinguishes the unubiquitinated and monoubiquitinated forms. The testing is useful in three situations for screening FA mutations: (1) in FA patients with diagnostic MMC-induced chromosomal breakage assays, FANCD2 null mutations are presumed if no full-length FANCD2 is detected by immunoblotting; (2) if FANCD2 is detected but is not monoubiquitinated, mutations of one of the upstream core complex genes are predicted; and (3) if FANCD2 is detected and is monoubiquitinated, a mutation of FANCD1/BRCA2, FANCJ/BACH1/BRIP1, FANCN/PALB2, FANCO/Rad51C, or FANCP/SLX4 is expected because all five localize downstream of FANCD2. Monoubiquitination of FANCD2 is normal in other BM failure syndromes and chromosomal breakage disorders.

Other Findings. Fanconi anemia cells exposed to alkylating agents arrest in the G_2/M phase of the cell cycle. The transfected wild-type FA gene that reduces G_2/M arrested cells as determined by cell cycle kinetics using flow cytometry pinpoints the mutant gene.

Apparently, the majority of FA patients have stable, elevated levels of serum α-fetoprotein expressed constitutively that are independent of liver complications and of androgen therapy. Levels are also unchanged after HSCT. The clinical utility of these findings is limited.

Ultrasonographic examination of the abdomen may reveal congenital anomalies of the kidneys and urogenital system. Echocardiography may reveal cardiac anomalies. Radiography and computed tomography (CT) can be informative in revealing bone, intestinal, or other anomalies. Imaging using radiation should be minimized as much as possible because of the carcinogenic risk.

Predisposition to Malignancy

A major feature of the FA phenotype is the propensity to develop cancer. The chromosome fragility, the defects in DNA repair, the genomic instability, and the cellular damage that occur in FA patients translate into a significant predisposition to develop a malignancy. Because there are at least 15 genetic mutations that lead to FA and alterations in the FA pathway are relevant to the pathogenesis of common types of cancers, the disorder is a critical human model of the genetic determinants of hematologic cancers and solid tumors.

Fanconi anemia is a member of two families of cancer predisposition syndromes. The first is composed of genetic disorders of DNA repair that include ataxia telangiectasia, xeroderma pigmentosum, and Bloom syndrome. The close relationship between FA and ataxia telangiectasia, for example, is underscored by data showing convergence of signaling pathways in both conditions. The second family of predisposition syndromes consists of other inherited BM failure disorders described herein, including SDS and DC that show a propensity for malignant myeloid transformation or solid tumors.

The magnitude of the risk of developing malignancy in FA has been defined in three comprehensive reports: a literature review of more than 2000 published cases, the IFAR prospective registry of 754 patients, and a retrospective North American cohort survey of 145 cases. The median patient age for the development of all cancers in the literature review was 16 years of age, which is strikingly different from the median age of 68 years for the same types of cancer in the general population. It was apparent from the three reports that the crude risk of cancer in FA patients is extraordinarily high: 5% to 10% for leukemia, about 5% for MDS, and 5% to 10% for solid tumors. The IFAR data indicate that by the age of 40 years, the cumulative incidence of leukemia and nonhematologic cancers is 33% and 28%, respectively.

The literature review identified 175 cases of leukemia, mostly AML, and 110 cases of MDS. Previous observations by the IFAR showed that the risk of developing MDS and AML was higher for patients in whom a prior clonal BM cytogenetic abnormality had been detected. Monosomy 7, rearrangement or partial loss of 7q, rearrangements of 1p36 and 1q24-34, and rearrangements of 11q22-25 are frequent recurring cytogenetic clonal changes. Additional data indicate a strong correlation in FA BM cells of chromosome 3q26q29 partial trisomies and tetrasomies and rapid progression to MDS or AML. When interpreting the significance of clonal cytogenetic abnormalities in FA patients, note that clonal variation is frequent, including appearances of new clones, inability to detect established clones on repeat examination, and clonal evolution. Similar to the literature review, the IFAR verified that the risk of developing hematologic and nonhematologic cancer in FA increased with advancing age, but the IFAR did not show an age-related plateau for the risks for MDS and AML, possibly because both diagnoses were analyzed together.

The literature review also identified 320 patients with other forms of cancer, 25 of whom had up to three separate types of solid tumors, and 14 additional cases of solid tumors who also had leukemia. None of these patients had received a BMT before developing cancer. The most frequent solid tumor reported was squamous cell carcinoma involving head and neck and upper and lower esophagus followed by the vulva or anus, cervix, and skin. There were additional cases of tongue and oral squamous cell carcinoma that occurred after HSCT. Liver tumors, benign and malignant, were second most frequent. Most of these hepatoma and adenoma patients had received prior androgen therapy for aplastic anemia. Androgen administration has therefore been implicated in liver tumor pathogenesis. In descending order of frequency, cancers were also reported in brain, kidney, breast, and adrenal gland. The IFAR 20-year prospective observational study and the North American cohort survey corroborated the literature review in terms of type of cancer, site, and risk.

Heterozygote Phenotype

Heterozygote carriers of FANC gene mutations do not develop peripheral blood cytopenias or aplastic anemia, and cell lines from heterozygote carriers do not show excessive chromosome fragility in culture when exposed to DEB or MMC. The mean chromosomal breakage level of lymphocytes from FA carriers tested in cultures with a clastogenic agent may be higher than controls, but individual carrier testing may show overlap with normal values and severely limits its diagnostic utility. Literature from the early 1980s describes congenital anomalies of the hand and the genitourinary system in relatives of patients with FA, and parents of children with FA may have short stature. FA carriers may have increased levels of HbF, decreased natural killer (NK) cell counts, and diminished reactivity to mitogen stimulation.

Monoallelic carriers for *FANCD1, FANCN,* and *FANCJ* are at increased risk of developing cancer. Female carriers of *FANCD1* have an increased risk of breast cancer ranging from 40% at age 80 years to a lifetime risk of about 80%. Carriers also are predisposed to develop ovarian cancer with a risk of up to 20% at age 70 years. Male carriers have a 7% risk of breast cancer and a 20% risk of prostate cancer before age 80 years. Mutant FANCN and FANCJ are low-penetrance breast cancer susceptibility alleles with about a twofold increased risk in carriers compared with the general population.

Differential Diagnosis

About 30% of FA patients do not have physical anomalies, and such individuals may not be recognized until they present with aplastic anemia, MDS, AML, unilineage cytopenias, or macrocytic RBCs. Thus, FA should be part of the differential diagnosis in children and adults with unexplained cytopenias, characteristic birth defects, a diagnosis of aplastic anemia, MDS or AML in patients up to the age of 40 years and possibly higher, unusual sensitivity to chemo- or radiotherapy, cancer typical of FA but at an atypical age such as cancer of the cervix when younger than 30 years, or squamous cell carcinoma of the head and neck when younger than 50 years of age. Any of these should prompt consideration of FA as the underlying problem. All patients with idiopathic aplastic anemia who are younger than 40 years should have chromosomal fragility testing. However, if the test was not performed at diagnosis, patients with "idiopathic" aplastic anemia who fail to respond to immunosuppressive therapy with ATG and cyclosporine should be tested.

Although neutropenia is a consistent feature of SDS, anemia or thrombocytopenia (or both) is seen in more than 50% of the patients and can be confused with FA. Because growth failure is also a manifestation of SDS, differentiating between the two disorders can initially be difficult. The major difference between them is that SDS is a disorder of exocrine pancreatic dysfunction that produces gut malabsorption. This can be confirmed by fecal fat analysis; by pancreatic stimulation studies using intravenous secretin or cholecystokinin that confirm markedly impaired enzyme secretion; and by showing reduced levels of serum trypsinogen, serum isoamylase, or fecal elastase. CT, ultrasonography, or magnetic resonance imaging (MRI) of the pancreas may also demonstrate fatty changes within the pancreatic body. Other skeletal distinguishing features found in some patients with SDS are short flared ribs, thoracic dystrophy at birth, delayed bone maturation, and metaphyseal dysostosis of the long bones. Chromosomes analyses do not show spontaneous breaks in SDS, and there is no increased breakage after clastogenic stress testing using DEB or MMC. Specific diagnostic confirmation is obtained by demonstrating the mutant *SBDS* gene.

Dyskeratosis congenita shares some features with FA, including development of pancytopenia, a predisposition to cancer and leukemia, and skin pigmentary changes. However, the pigmentation pattern is somewhat different in DC and manifests with a lacy reticulated pattern affecting the face, neck, chest, and arms, often with a telangiectatic component. At some point, usually in the first decade of life, DC patients also develop dystrophic nails of the hands and feet and, somewhat later, leukoplakia involving the oral mucosa, especially the tongue. Other findings seen only in DC and not in FA are teeth abnormalities with dental decay and early tooth loss, hair loss, and hyperhidrosis of the palms and soles. Chromosomal fragility

with DEB testing is normal in DC patients, who contrast sharply with FA patients. In the X-linked form of DC, mutations can be identified in the *DKC1* gene. A *TERC, TERT,* or *TINF2* gene mutation confirms an autosomal dominant form of the disorder. A *NOP10* or *NHP2* mutation accounts for autosomal recessive DC.

Congenital amegakaryocytic thrombocytopenia (CAMT) and **TAR syndrome** both manifest in the neonatal period with thrombocytopenia. A neonatal hematologic presentation is atypical for FA; fewer than 5% of patients are diagnosed during the first year of life. Neither of the thrombocytopenic syndromes shows chromosome fragility, which separates them from FA, and a mutant *MPL* gene is diagnostic of CAMT. In the TAR syndrome, thumbs are always preserved and intact despite the absence of radii, but in FA, the thumbs are hypoplastic or absent when the radii are absent.

Seckel syndrome, or **"bird-headed dwarfism"** manifests with short stature; microcephaly; cognitive delay; sinopulmonary infections; and a predisposition to developing lymphomas, pancytopenia, and AML. Some patients may show increased chromosomal breakage in lymphocyte cultures with DEB or MMC and mimic FA. There are possibly four genes linked to Seckel syndrome: mutant *ATR* has been confirmed for Seckel 1 subtype, and mutant *CENPJ* has been postulated to account for Seckel 4 subtype. Genotyping will distinguish FA from Seckel syndrome.

Nijmegen breakage syndrome (NBS) is an autosomal recessive disorder caused by mutations in the *NBS1* gene and is characterized by stunted growth, microcephaly, a distinctive facies, café-au-lait spots, immunodeficiency, and a predisposition to lymphoid malignancy. Some patients resemble those with FA, have BM failure, and may show increased chromosome breakage in lymphocyte cultures with MMC. The genetic defect is a mutant *NBS1* gene whose wild-type protein product is involved in DNA repair. Because NBS can mimic and be confused with FA, genotyping is essential and diagnostic.

Cells from patients with **Bloom syndrome** show abnormal spontaneous breakage, but unlike FA cells, the breakage does not increase in vitro in response to DEB. **Ataxia telangiectasia** is characterized by sister chromatid exchange without hypersensitivity to DEB or BM failure.

Natural History and Prognosis

The most serious early consequence in most FA patients is BM failure. The exceptions are patients with biallelic FANCD1/*BRCA2* mutations who have a cumulative probability of 97% of developing a malignancy by age 6 years, including AML, Wilms tumor, and medulloblastoma. Judging from the literature, the overall risk for FA patients developing solid malignant tumors, liver tumors, acute leukemia, and MDS is at least 15%, but it is likely higher in older patients. Treatment for cancer imposes additional problems and probably increases the risk for additional cancers secondary to therapy. Thus, the major causes of death in FA are sepsis and bleeding from BM failure, complications of HSCT, and progressive cancer or consequences of its treatment.

Despite these serious issues, the prognosis for FA patients is improving. Based on a literature review of more than 2000 FA case reports, the median survival from 1927 to 1999 was 21 years. In contrast, the median survival from 2000 to 2009 was 29 years of age. FA patients are now predicted to reach adulthood because more than 80% of patients reach age 18 years or more. Earlier diagnosis, especially of mild cases, diagnosis of FA in young adults with AML or a solid tumor, comprehensive clinical and laboratory surveillance programs, timely therapeutic interventions, and HSCT are attributed to the improved outlook.

Therapy

Because of their clinical and psychosocial complexity, patients with FA should be supervised by a hematologist at a tertiary care center using a comprehensive and multidisciplinary approach (see www.fanconi.org for *Fanconi Anemia Guidelines for Diagnosis and Management,* 3rd edition, 2008). On the initial visit, the practitioner should take a detailed personal and family history, a careful physical examination with emphasis on physical anomalies, complete blood counts and chemistries, a BM biopsy for cellularity and morphology, and an aspirate for additional morphology, cytogenetics, and an iron stain for ringed sideroblasts. DEB or MMC chromosome fragility testing on peripheral blood lymphocytes on patients and siblings should be arranged. If FA is confirmed by DEB or MMC testing, the complementation group assignment and mutation analysis can be initiated. On a separate visit, imaging studies should be requested to search for internal anomalies. When all the results from the workup have been compiled, a follow-up visit with the patient and family is arranged to discuss the diagnosis, management options, and prognosis. A referral to a genetic counselor should ensue. High-resolution human leukocyte antigen (HLA) typing of the patient and immediate family members is recommended shortly after the diagnosis is established to determine potential matched-related donors in case HSCT becomes necessary.

If the patient is stable, has only minimal to moderate hematologic changes, and does not have transfusion requirements, a period of observation is indicated. During this time, subspecialty consultations (e.g., with orthopedic surgeons, urologists, gynecologists, and otolaryngologists) can be arranged during this interval. Blood counts should be monitored every 1 to 3 months to determine their stability. In a stable patient with mild cytopenias, blood counts can be monitored every 3 months, and BM evaluation should be performed annually. Falling counts, a clonal BM cytogenetic abnormality, or prominent multilineage dysplasia require more frequent clinic visits and blood and BM sampling to monitor for progression to severe aplastic anemia, AML, or MDS. Spectral karyotyping (SKY), fluorescent in situ hybridization (FISH), and comparative genomic hybridization of BM cells can enhance the diagnostic capability.

A surveillance program for solid cancers should be initiated at least annually. After the age of 10 years or after HSCT, the oral cavity should be examined every 6 months for signs of malignant change because the risk in untransplanted FA patients is 700-fold that of the general population. Oral cancers can occur within 1 year after HSCT. Dentists, oral surgeons, or head and neck surgeons should be recruited after the age of 10 years or after HSCT to screen for head and neck squamous cell carcinomas by rhinopharyngoscopy using a flexible endoscope. Beginning at age 13 years, all women with FA should undergo annual gynecologic screening because the relative risk of vulvar squamous cell carcinoma is 4000-fold higher and cervical cancer is 200-fold higher than that of the general population. Human papilloma virus (HPV) DNA can be detected in 84% of FA squamous cell carcinoma specimens from various anatomic sites. Although the role of HPV in FA carcinogenesis is controversial, quadrivalent HPV vaccine is still recommended for boys and girls with FA at 9 years of age as a possible preventive approach.

Growth should be serially documented, and when growth velocity or stature falls below expectations, endocrine evaluation is needed to identify growth hormone deficiency. Impaired glucose tolerance, hyperinsulinemia, and diabetes mellitus occur more commonly in FA, and patients should be screened annually or biannually depending on the degree of hyperglycemia found on initial testing. Screening for hypothyroidism also should be performed annually.

Hematopoietic Stem Cell Transplantation

Hematopoietic stem cell transplantation is the only curative therapy for the hematologic abnormalities of FA: aplastic anemia, AML, and MDS. The best donor source is an HLA-matched sibling in whom thorough history, physical examination, blood counts, HbF, chromosome breakage testing, and ideally genetic testing have excluded a diagnosis of FA. Initial efforts to transplant FA patients using standard preparative regimens and graft-versus-host disease (GVHD) prophylaxis were plagued by two serious and often lethal problems, severe cytotoxicity from chemotherapy and irradiation and

exaggerated GVHD. Reduced-intensity HSCT protocols that remain myeloablative for FA patients were subsequently introduced and improved outcomes ensued. Research is constantly ongoing for the most effective strategies.

Absolute indications for a matched sibling donor HSCT are (1) severe underproductive cytopenias and transfusion dependency; (2) high-risk MDS with chromosomal clonal abnormalities like monosomy 7, or partial trisomies and tetrasomies of 3q26q29, or a BM blast count of greater than 5%; or (3) overt AML. Serious consideration for transplantation should also be considered for FA with high-risk mutations for AML such as biallelic *FANCD1/BRCA2*. Decision to transplant for milder, relative indications should be made on a case-by-case basis.

Three caveats about transfusional supportive care before HSCT are (1) more than 20 exposures to blood products is a risk factor that adversely affects engraftment and survival posttransplant; (2) use of directed donations from family members may cause alloimmunization to an antigen that can increase the risk of graft rejection after a matched sibling donor or haploidentical related HSCT; and (3) single-donor apheresis platelets should be requested when required and the product should be leukodepleted and irradiated.

Cytoreductive regimens for matched sibling donor HSCT have gradually excluded total-body irradiation (TBI). Most published studies have adopted one of the following protocols: (1) cyclophosphamide, ATG, and TBI; (2) fludarabine, cyclophosphamide, and ATG; or (3) cyclophosphamide alone. Fludarabine, a purine antimetabolite with potent immunosuppressive and myeloablative properties with minimal toxicity to other tissues, continues to gain favor as an effective adjunct to preparative regimens. Some centers currently prefer fludarabine, cyclophosphamide, and TBI because of improved rates of engraftment, reduction of T-cell mosaicism and its deleterious effects, and improved survival. All four regimens are successful and have their advocates. Transplant centers usually intensify the cytoreductive regimen when the patient has MDS or AML. Disease-free survival data for TBI-based protocols vary between 64% and 89%. Disease-free survivals for non-TBI protocols are as high as 93% using cyclophosphamide alone. The risk of primary or secondary graft failure is 5% to 10%, and the risk of acute GVHD ranges from 8% using cyclosporine and methotrexate prophylaxis to 55% using cyclosporine alone.

Hematopoietic stem cell transplantation using HLA-mismatched related donors, matched or one-antigen mismatched unrelated donors, or cord blood carries a higher risk of complications and a lower disease-free survival than matched sibling donor HSCT. The best outcome predictors are recipients younger than 10 years old, recipient seronegativity for CMV, history of fewer than 20 exposures to blood products, and use of fludarabine in the cytoreductive regimen. Risk factors adversely affecting survival are an HLA-mismatched donor, an FA phenotype with three or more congenital malformations, and prior administration of androgen therapy. The latter factor might be related to the delay in transplant rather than the therapy itself. Indications for an alternate donor HSCT are identical to those for a matched sibling donor HSCT.

Provided that no extended family members are suitable BM or peripheral blood stem cell donors, unrelated BM donors are sought and identified by searching donor and umbilical cord blood registries. An acceptable unrelated donor should be fully matched by high-resolution typing for all HLA-A, B, C, and DRB1 antigens, a so-called *8/8 match*. A second choice is a one-antigen mismatch in a BM donor. Matched or one-antigen mismatched banked umbilical cord blood is equally suitable to a one-antigen mismatched BM donor and is an option. The last choice is a two-antigen mismatched cord blood. Using cord blood cells from unrelated donors, engraftment and survival are comparable to related or unrelated BM, although engraftment is slower with cord blood. The incidence of acute and chronic GVHD is reduced with cord blood grafts even in 1 or 2 HLA antigen mismatched transplants. Three-year published survival rates after unrelated HSCT for FA range between 40% and 75%.

Molecular technology has led to preimplantation genetic diagnosis (PGD) coupled with in vitro fertilization. This is an option for parents who have a child with FA and a defined *FANC* mutation but without a matched sibling donor. If the mother is fertile, eggs are harvested and fertilized with the father's sperm in vitro, resulting in a number of blastomeres. Using single-cell polymerase chain reaction (PCR) technology, isolated cells from several blastomeres can be tested for an HLA match and for absence of the *FANC* mutation. The selected HLA-compatible normal blastomeres can then be transferred and implanted in utero, resulting in a successful pregnancy and subsequent birth of a matched unaffected sibling. Cord blood from the PGD-selected healthy infant sibling can be banked for a HSCT for the affected sibling. The notion of "designer babies" is still debated in ethical circles.

Despite the successes of HSCT in correcting the BM failure of FA patients, there is a subset of survivors who develop cancers, particularly squamous cell carcinoma of the head and neck. These malignancies reflect the ongoing genetic susceptibility of FA nonhematopoietic tissue to cancer despite successful transplantation for aplastic anemia, MDS, or AML. Published data comparing cancer risks in transplanted and nontransplanted FA patients show a 4.4-fold increase in age-specific hazard rate of squamous cell carcinoma in the transplanted cohort. The causes for the increased cancer risk are not proven, but GVHD, especially chronic, and the preparative regimens of chemotherapy and irradiation are highly suspect. T-cell depletion has been introduced in some protocols to reduce GVHD, and irradiation has been reduced or eliminated in others to address this issue.

G-CSF mobilization and collection of peripheral blood $CD34^+$ cells from FA patients before the onset of severe pancytopenia has not attained broad application. These cells in theory can be used as targets for gene therapy; however, their cryopreservation and infusion later when severe BM failure ensues or as an autologous rescue after chemotherapy in the event of leukemic transformation is unlikely to reconstitute the hematopoietic system or confer a survival benefit.

Hematopoietic Growth Factors

Both G-CSF and GM-CSF can induce a neutrophil response in neutropenic FA patients. G-CSF is indicated for a patient with recurrent or serious bacterial infection, especially if the neutrophil counts are less than $500/mm^3$. In a published clinical trial of G-CSF in 12 FA patients, all 12 had an increase in absolute neutrophil numbers, five had a significant increment in hemoglobin levels, and four had an increase in platelet counts. Concurrent with the impressive improvements in blood counts, 8 of 10 patients who finished 40 weeks of G-CSF treatment showed elevations in the percentage of BM and peripheral blood CD34+ cells. The starting dose for subcutaneous G-CSF is 5 μg/kg/day, and after a neutrophil response occurs, the dose can be decreased to every second day or 2 to 3 times a week. Long-acting pegylated G-CSF has not been studied in FA.

In another published clinical trial, combination cytokine therapy consisting of subcutaneous G-CSF 5 μg/kg once daily with erythropoietin 50 units/kg administered subcutaneously or intravenously three times a week was given to FA patients. Androgen therapy was added if the response was inadequate. Of 20 patients treated, 19 had improved neutrophil numbers, 6 had an increase in hemoglobin levels, and 4 achieved a sustained rise in platelets.

Because genomic instability and a marked predisposition to leukemia and cancer are features of FA, the wisdom of using granulopoietic growth-promoting cytokines on a long-term basis for FA is an issue. There may be a heightened risk of inducing or promoting expansion of a leukemic clone, especially one with monosomy 7. Therefore, before starting cytokine therapy, a baseline BM aspirate and biopsy is recommended and then repeated every 6 months to document changes in morphology and cytogenetics.

Androgens

Androgen therapy has been used to treat FA for decades. The overall response rate in the literature is about 50% heralded by

reticulocytosis and a rise in hemoglobin within 1 to 2 months. If the other lineages respond to androgens, white blood cells increase next and then platelets, but it may take many months to achieve the maximum response. When the response is deemed maximal, the androgens should be slowly tapered but not stopped entirely. Accepted indications for treating with androgens are one or more of the following: hemoglobin level less than 8 g/dL or symptoms from anemia, platelet count less than 30,000/mm^3, and neutrophil count less than 500/mm^3. Oxymetholone, an oral 17-α alkylated androgen, is used most frequently at 1 to 5 mg/kg once a day. The authors' practice is to start with 0.5 mg/kg/day and increase it monthly if there are no major side effects and an insufficient response. Although unproven, some clinicians add corticosteroids to offset androgen-induced growth acceleration and to prevent thrombocytopenic bleeding by promoting vascular stability. For this purpose, 5 to 10 mg of prednisone is given orally every second day. If an injectable androgen is preferred to decrease the risk of liver toxicity and growth of hepatic tumors, nandrolone decanoate, 1 to 2 mg/kg/wk, is given intramuscularly followed by the application of local pressure and ice packs to prevent the development of hematomas. There are insufficient comparative data on the efficacy of the attenuated androgen, Danazol, compared with oxymetholone to make a recommendation, but a Danazol clinical trial for FA at Children's Hospital Boston is underway. Another androgen, oxandrolone, is also in clinical trial for FA at Cincinnati Children's Hospital. Claims of reduced masculinizing side effects in female FA patients treated with Danazol compared with those treated with oxymetholone have not been substantiated in clinical trials.

Almost all patients relapse when androgens are stopped. The few who successfully discontinue treatment are often in the puberty age range when temporary "spontaneous hematologic remissions" have been observed to occur. Most patients on long-term androgens eventually become refractory to therapy as BM failure progresses. Potential side effects include masculinization, which is especially troublesome in female patients, and elevated hepatic enzymes, cholestasis, *peliosis hepatis,* and liver tumors. Five complications of androgen therapy require consideration.

1. *Peliosis hepatis* is a cystic dilation of hepatic sinusoids that fill with blood and can be life threatening if they rupture. They may be clinically silent or produce right upper quadrant pain. Liver function test results are normal. Ultrasonographic examination is a safe way to diagnose the abnormality. The lesions may regress after stopping the androgens.
2. *Androgens also damage hepatocytes* nonspecifically. This may be manifest as cholestatic jaundice or elevated liver enzymes. Stopping androgen therapy usually leads to complete resolution. Hepatic cirrhosis may develop in patients on continued androgen therapy. If resolution of enzyme elevation does not occur after androgen withdrawal, a liver biopsy is indicated.
3. *Hepatocellular adenomas* are associated with androgen therapy. These are benign, noninvasive tumors. They can, however, rupture, leading to life-threatening bleeding. FA patients may develop these tumors rapidly, but they can be readily detected by imaging. The tumor may regress after stopping the androgens. If persistent, surgical resection or radiofrequency ablation may be necessary.
4. *Hepatocellular carcinoma* (HCC; hepatoma) occurs with androgen use, and some studies have suggested that FA patients on treatment may be at increased risk for HCC. The HCC associated with androgens characteristically does not produce α-fetoprotein in serum, distinguishing it from de novo HCC. Patients developing HCC should discontinue androgen therapy.
5. Androgen therapy for FA patients is recognized by HSCT physicians as an important *adverse prognostic factor* for those receiving a transplant. Several centers with experience in FA transplants firmly recommend that androgens *not* be given to FA patients unless a suitable donor cannot be identified. The cause of the association is unknown but may be related to delay in HSCT rather than the drug itself.

Those receiving androgens should be evaluated serially with liver enzyme profiles every 2 to 3 months and ultrasonography or CT scan of the liver every 6 to 12 months. If liver enzymes increase to above normal or if abnormalities appear on imaging, the androgen dose should be decreased or stopped. It is strongly recommended by many transplant centers that an FA patient not receive androgens if it is known that the patient has a matched donor available.

Future Directions

The premise for gene therapy in FA is based on the assumption that corrected hematopoietic cells would have a growth advantage. Strengthening this supposition are FA patients with hematopoietic somatic mosaicism who show spontaneous disappearance of cells with the FA phenotype. These *mosaic* patients may show spontaneous hematologic improvement, suggesting that hematopoiesis was derived from stem cells with a normal phenotype. In the context of gene therapy, evidence suggests that even one genetically corrected HSC may be able to repopulate the BM of an FA patient.

Despite encouraging preclinical studies more than a decade ago using retroviral vectors showing that wild-type *FANCC* and *FANCA* could be integrated into normal and FA $CD34^+$ cells, the ensuing clinical trials in *FANCC* and *FANCA* patients were disappointing, and gene therapy still remains at a developmental stage. A central problem is suboptimal wild-type gene integration into FA cells in culture. Because of the apoptotic phenotype and the sensitivity to oxidative stress, FA cells die rapidly in vitro before efficient gene transfer is accomplished. Changing the tissue culture conditions and introducing lentiviral vectors that can infect noncycling human cells were deemed the solutions, but obstacles persist. Ongoing research is directed at novel vector design, transduction methodology, and improved strategies for preparing HSCs. One caveat: a successful FA gene therapy protocol may correct BM failure and possibly the propensity for MDS and AML, but the predisposition for cancer in other tissues will continue unchecked.

Shwachman-Diamond Syndrome

Shwachman-Diamond syndrome is an autosomal recessive multisystem disorder characterized by varying degrees of BM failure, a high risk of leukemia, and exocrine pancreatic insufficiency. Additional features may include short stature and skeletal abnormalities. The mutant gene responsible for this complex pleiotropic phenotype, termed *Shwachman-Bodian-Diamond syndrome (SBDS),* has been identified and has been confirmed in 90% of patients with the classic presentation. *SBDS* seems to be multifunctional and promotes cell survival, ribosome biogenesis, mitotic spindle stability, and chemotaxis. To date, though, no unifying pathogenesis has been able to account for all of the multisystem features of SDS.

Epidemiology

Shwachman-Diamond syndrome has been reported among all ethnic groups. Older studies suggested a higher incidence in males. However, recent data suggest an equal distribution between genders as expected from an autosomal recessive disorder. Based on data from the CIMFR, SDS is the third most common inherited BM failure syndrome with an incidence of 8.5 cases per million live births.

Pathobiology

The identification of *SBDS* on chromosome 7q11 was the entry point for studies on the molecular basis for SDS. There is an adjoining pseudogene *(SBDSP)* with 97% homology in its coding regions to *SBDS*. The gene encodes a 250 amino acid protein product, which is a member of a highly conserved protein family of previously

unknown function with putative orthologs in diverse species, including Archaea and eukaryocytes. Based on structural studies of the ortholog in Archae and the human protein, the SBDS protein has three main domains (N-terminal, middle, and C-terminal) with predicted protein–protein, protein–DNA, and protein–RNA binding motifs.

The common *SBDS* mutations are composed of sequences that are homologous to *SBDSP*. Hence, these mutations are believed to result from recombination events whereby segments of *SBDSP* become incorporated into wild-type *SBDS* and interfere with its function. These recombinational events result in three common gene conversion mutations in exon 2 that account for 75% of *SDS* alleles: (1) a nonsense mutation, 183_184TA>CT, introduces an in-frame stop codon (K62X); (2)) a splice-site mutation, 258+2T>C, which may either cause premature truncation of the SBDS protein by frameshift (C84fs3) or use an alternative splice site; and (3) an extended conversion mutation, 183_184TA>CT and 258+2T>C, encompasses both mutations. In the Toronto database of 210 SDS families, 89% of unrelated SDS individuals carry a gene conversion mutation on one allele, and 60% carry conversion mutations on both alleles. Thus, the vast majority of patients are compound heterozygotes with respect to K62X and C84fsx3. Additional rare mutations in the *SBDS* gene have been identified in SDS patients. These include dozens of insertion, deletion, and missense mutations that have not arisen from gene conversion events. Most *SBDS* mutations alter the N-terminal domain of the protein and lead to markedly reduced protein levels.

SBDS protein is essential for life because no patients with homozygous null mutations have been reported, and residual protein levels can usually be detected in SDS patients. Furthermore, a complete loss of the protein in mice causes developmental arrest before embryonic day 6.5 and early lethality. SBDS seems to be multifunctional and play a role in several cellular pathways, including ribosomal biogenesis, cell survival, chemotaxis, mitotic spindle formation, and protection from cellular stress.

The SBDS protein phylogeny is shared with proteins that are enriched for RNA metabolism and/or ribosome-associated functions. The SBDS protein can be detected in human cell nuclei and cytoplasm. It concentrates in the nucleolus during G1 and G2. Synthetic genetic arrays of YHR087W, a yeast homolog of the N-terminal domain of SBDS, suggested interactions with several genes involved in RNA and rRNA processing. Loss of the protein in humans and yeast results in failure to remove eukaryotic initiation factor 6, eIf6 or its homologue in yeast, Tif6, from the ribosomal large subunit in the cytoplasm and impairs the assembly of the large and small ribosome subunits to form the mature ribosomes. SBDS directly interacts with the GTPase elongation factor-like 1 (EFL1). The interaction promotes eIF6 removal from the 60S subunit by a mechanism that requires guanosine triphosphate (GTP) binding and hydrolysis by EFL1. SBDS interacts with multiple proteins with diverse molecular functions; many of them are involved in ribosome biogenesis, such as RPL4, and DNA metabolism, such as RPA70.

SBDS is critical for cell survival. When *SBDS* is lost in SDS BM cells or in *SBDS*-knockdown K562 and HeLa cells, the cells undergo accelerated apoptosis. The accelerated apoptosis in BM cells and *SBDS*-knockdown cells seems to be through the Fas pathway and not through the Bax/Bcl-2/Bcl-XL pathway. SBDS deficiency in primary SDS cells and in *SBDS*-knockdown cells results in abnormal accumulation of functional Fas at the plasma membrane level.

Patients with SDS have a defect in leukocyte chemotaxis. Consistent with this observation, the *SBDS* homologue in amoeba was found to localize to the pseudopods during chemotaxis. These observations suggest that the *SBDS* protein deficiency in SDS causes a chemotaxis defect in patients.

Shwachman-Bodian-Diamond syndrome has been shown to colocalize to the mitotic spindle and bind microtubles and stabilize them. Its deficiency results in centrosomal amplification and multipolar spindles.

The pathophysiologic link between *SBDS* mutations and BM failure is still unclear. Initial studies in the 1970s and early 1980s showed reduced CFU-GM and BFU-E colony formation in most patients compatible with a defective stem cell origin of the BM failure. Recent investigations have characterized a much more extensive hematopoietic phenotype (Table 27-3). SDS BM has decreased numbers of $CD34^+$ cells as well as an impaired ability for $CD34^+$ cells to form multilineage hematopoietic colonies in vitro, confirming that they are intrinsically defective. Patients' BM cells overexpress Fas, the membrane receptor for Fas ligand, and show increased patterns of apoptosis after preincubation with activating anti-Fas antibody, pinpointing this as a central pathogenetic mechanism for the BM failure. Induction of differentiation (at least toward erythroid lineage) results in markedly accelerated apoptosis in SBDS-deficient cells, with only a minimal effect on proliferation. Importantly, oxidative stress is increased during differentiation of SBDS-deficient erythroid cells, and antioxidants enhance the expansion capability of both differentiating *SBDS*-knockdown K562 cells and colony production of SDS patient HSCs and progenitors. Erythroid differentiation also results in reduction of all ribosomal subunits and global translation. These studies indicate that when *SBDS* protein is deficient, several biologic pathways may be dysfunctional during hematopoietic cell development; this may be the cause of the high predilection for BM failure in patients with SDS.

Two other abnormalities have been identified in SDS. When the averages of telomere lengths adjusted to age are compared with those of control participants, a tendency toward shortening of telomeres is found in patient leukocytes, reflecting premature cellular aging. This may represent either an inherent defect in telomere maintenance or compensatory stem cell hyperproliferation. In addition to an inherent hematopoietic defect, it has also been shown that the BM stroma is markedly defective in terms of its ability to support and maintain normal hematopoiesis.

Clinical Features

The many clinical manifestations that occur in varying combinations are shown in Table 27-4. Most patients present in infancy with evidence of growth failure, feeding difficulties, diarrhea, and infections. Steatorrhea and abdominal discomfort are frequent. Approximately 50% of patients exhibit a modest improvement in pancreatic function and do not require further pancreatic enzyme replacement therapy. Hepatomegaly is a common physical finding in young children but typically resolves with age and does not have clinical significance.

Patients with SDS are particularly susceptible to bacterial and fungal infections, including otitis media, bronchopneumonia, osteomyelitis, septicemia, and recurrent furuncles. Overwhelming sepsis is a well-recognized fatal complication of this disorder, particularly early in life.

Short stature is fairly consistent feature of the syndrome. When treated with pancreatic enzyme replacement, most patients show a

Table 27-3 Hematopoietic Phenotype in Shwachman-Diamond Syndrome

Decreased BM $CD34^+$ cells
Decreased colonies from $CD34^+$ cells
Abnormal telomere shortening of leukocytes
Increased apoptosis of BM cells
Apoptosis is mediated by Fas pathway
Impaired BM stromal cell function
Abnormal lymphoid immune function
Increased BM microvessel density
BM cell upregulation of specific oncogenes
Increased levels of reactive oxygen species
Accentuation of the ribosome biogenesis defects with reduced ribosome subunits, ribosomes, and polysomes
Accentuation of the protein translation defect

BM, Bone marrow.

Table 27-4 Clinical and Hematologic Features of Shwachman–Diamond Syndrome

Major Features	Patients (%)
Pancreatic insufficiency (decreased digestive enzymes)	86-100
HEMATOLOGIC CYTOPENIAS	
Neutropenia	88-100
Thrombocytopenia	24-70
Anemia	42-66
Pancytopenia	10-44
MDS/AML	≈30
Other Features	
Short stature	50
Delayed bone maturation	100
Metaphyseal dysplasia	44-77
Rib cage anomalies	32-52
Hepatomegaly or elevated enzymes	<50
Poor oral health (caries, ulcers, tooth loss)	>50
Learning and behavioral problems	>50

AML, Acute myeloid leukemia; *MDS,* myelodysplastic syndrome.

normal growth velocity yet remain consistently below the third percentile for height and weight, indicating an intrinsic growth defect. The occasional adult achieves the 25th percentile for height. Although metaphyseal dysplasia is a common radiologic abnormality (44%-77% of patients), particularly in the femoral head and the proximal tibia, in most patients it fails to produce any symptoms. Occasional patients have clinical joint deformities, resulting in pain, functional impairment, or cosmetic problems, necessitating surgery. Some patients present at birth with respiratory distress caused by thoracic dystrophy. Others may have asymptomatic short and flared ribs.

The majority of the patients have deficits in cognitive abilities at varying levels of severity. These include delayed language development, low intellectual ability, impaired visual-motor integration, and failure to achieve higher order language functioning and problem solving. About one-fifth of the children have behavioral challenges such as attention deficit hyperactivity disorder, pervasive developmental disorder, or oppositional defiant disorder.

Some additional clinical features are seen very infrequently in SDS. Endocrine abnormalities include insulin-dependent diabetes, growth hormone deficiency, hypogonadotropic hypogonadism, hypothyroidism, and delayed puberty. Cardiomyopathies have been noted in some cases. Urinary tract anomalies, renal tubular acidosis, and cleft palate also occur.

Laboratory Findings

Peripheral Blood and Bone Marrow Findings. Published data accurately represent the spectrum of hematologic findings (see Table 27-4). Neutropenia is present in almost all patients on at least one occasion. The neutropenia can be chronic or intermittent. Neutropenia has been identified in some SDS patients in the neonatal period during an episode of sepsis. Anemia is recorded in about half of the patients. RBC MCV and fetal hemoglobin are elevated in 60% and 75% of the patients, respectively, after the age of 1 year. Whether this reflects stress hematopoiesis or ineffective erythropoiesis concomitant with chronic infections has not been clarified. The combination of isolated neutropenia and high MCV or high HbF after the first year of life is seen in up to 28% of SDS patients and almost never in other IBMFSs. Reticulocyte responses are inappropriately low for the levels of hemoglobin in 75% of patients. Thrombocytopenia can be seen in about 40% of the patients.

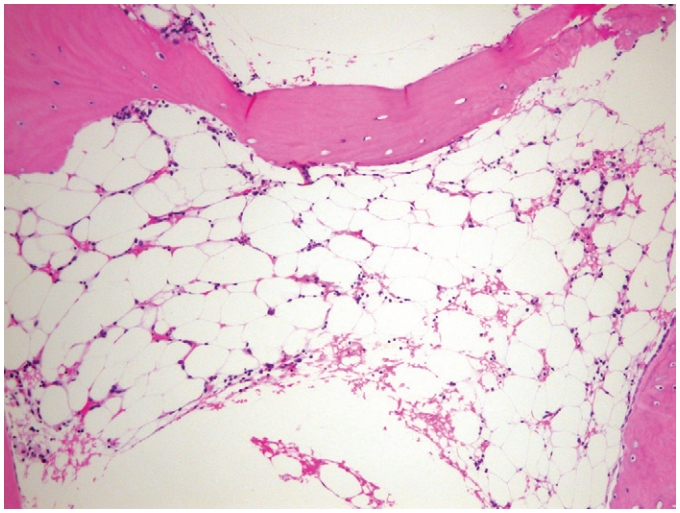

Figure 27-2 BONE MARROW BIOPSY IN SEVERE SHWACHMAN-DIAMOND SYNDROME SHOWING STRIKING HYPOCELLULARITY, FATTY CHANGES, AND TRILINEAGE APLASIA. *(Courtesy Dr. Mohamed Abdelhaleem, Toronto.)*

More than one lineage can be affected, and pancytopenia is observed in up to 65% of cases. The pancytopenia can be profound as a result of severe aplastic anemia (Fig. 27-2). However, BM biopsies and aspirates vary widely with respect to cellularity; varying degrees of BM hypoplasia and fat infiltration are the usual findings. BM with normal or even increased cellularity has also been observed, typically in young children. The severity of neutropenia does not always correlate with BM cellularity, nor is the severity of the pancreatic insufficiency concordant with the hematologic abnormalities.

Shwachman-Diamond syndrome neutrophils may have defects in mobility, migration, and chemotaxis. There appears to be a diminished ability of SDS neutrophils to orient toward a gradient of *N*-formyl-methionyl-leucyl-phenylalanine. An unusual surface distribution of concanavalin A has also been reported that reflects a cytoskeletal defect in SDS neutrophils. Whatever the magnitude of the chemotaxis abnormality is in vitro in SDS, neutrophil recruitment into abscesses or empyemas ensues robustly in vivo.

Immune Dysfunction. Impaired immune function can be significant in SDS and underlie recurrent infections even if adequate numbers of neutrophils are present. Patients have various B-cell abnormalities, including one or more of the following: low immunoglobulin G (IgG) or IgG subclasses, low percentage of circulating B lymphocytes, decreased in vitro B-cell proliferation, and lack of specific antibody production. Patients may also have T-cell abnormalities, including a low percentage of circulating T lymphocytes or subsets or NK cells, and decreased in vitro T-cell proliferation. Inverted CD4:CD8 ratios have also been described.

Exocrine Pancreatic Tests. The exocrine pancreatic pathology is caused by failure of pancreatic acinar development (Fig. 27-3). Pathologic studies reveal normal ductular architecture but extensive fatty replacement of pancreatic acinar tissue, which can be visualized by CT, ultrasonography, or MRI. Pancreatic function studies using intravenous secretin or cholecystokinin confirm the presence of markedly impaired enzyme secretion averaging 10% to 14% of normal but with preserved ductal function. Because of its invasive nature, this test has largely been replaced by measuring the levels of pancreatic enzymes in the serum.

During the first 3 years of life, serum trypsinogen is typically reduced and can be used for diagnostic purposes. Serum isoamylase

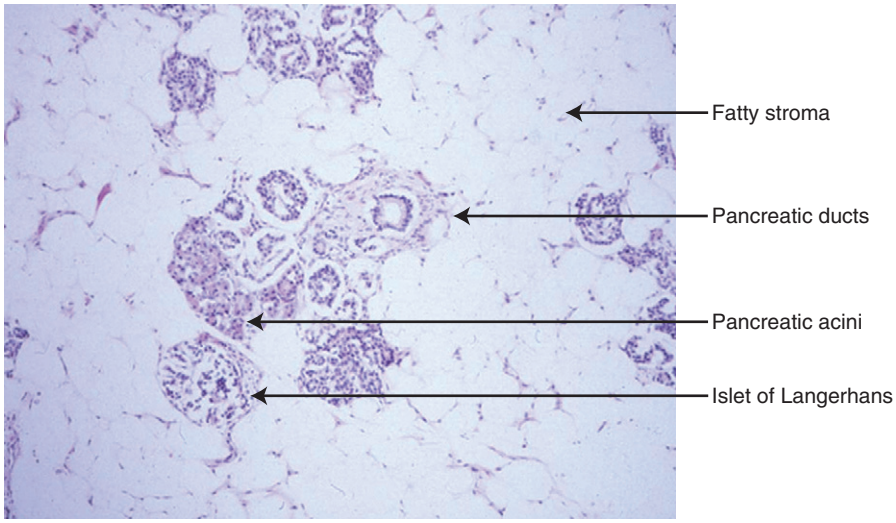

Figure 27-3 PANCREATIC TISSUE PATHOLOGY IN SEVERE SHWACHMAN-DIAMOND SYNDROME. The two classic features, deficiency of acinar tissue and fatty replacement, are shown. Islets of Langerhans are intact. *(Provided by Dr. Peter Durie, Toronto.)*

levels are low in SDS patients of all ages. However, normal children younger than 3 years have low isoamylase levels, so its measurement is not diagnostically useful at this age. Fecal elastase is another pancreatic enzyme that is reduced in SDS. Approximately 50% of patients exhibit a modest improvement in enzyme secretion with advancing age and normal fat absorption when assessed by 72-hour fecal fat balance studies. These patients do not require further pancreatic enzyme replacement therapy.

Skeletal Imaging. Radiographs of the bone are useful to establish a diagnosis. Osteopenia is seen in most patients but rarely results in clinical osteoporosis. Metaphyseal dysplasia has been reported in about 50% of the patients, particularly of the femoral heads, knees, humeral heads, wrists, ankles, and vertebrae. Rib-cage abnormalities can be found in 30% to 50% of patients. These include a narrow rib cage, short ribs, flared anterior rib ends, and costochondral thickening. Digital abnormalities such as clinodactyly, syndactyly, and supernumerary thumbs have been reported but are rare. Spinal deformities, including kyphosis and scoliosis, have been reported.

Imaging of the Brain. Patients with SDS do not have macroscopic brain malformations. However, they may have a decreased global brain volume (both gray matter and white matter) and a smaller posterior fossa, cerebellar vermis, corpus callosum, brainstem, and occipitofrontal head circumferences compared with control participants. These anomalies might be the basis for the neurocognitive and neurobehavioral difficulties.

Leukemia Predisposition. Shwachman-Diamond syndrome is characterized by a high propensity to develop MDS and leukemia, particularly AML. The published crude rate for MDS or AML (MDS/AML) in patients with SDS ranges from 8% to 33%. Of 55 SDS patients followed prospectively in the French Severe Chronic Neutropenia Registry, seven patients developed MDS or AML with an estimated risk of 19% at 20 years and 36% at 30 years. A literature search revealed 99 SDS cases with MDS/AML of whom 38 were reported as having leukemia either at first presentation with malignant transformation or after progressive MDS. Almost 90% of the patients had clonal BM cytogenetic abnormalities at transformation.

There is an increased frequency of BM clonal cytogenetic abnormalities as the sole evidence for a clonal disease in an otherwise hypocellular BM without excess blast counts or major prominent multilineage dysplasia. The incidence is roughly estimated to be 7% to 41% based on pooled published data. Isochromosome 7q [i(7q)], an extremely uncommon finding rarely described in MDS or AML in patients without SDS, was seen in 44% of SDS patients. This high occurrence suggests that it is a fairly specific marker for SDS and might be related to the mutant gene on 7q(11). Other chromosome 7 abnormalities are seen in 33% of SDS patients and include monosomy 7, i(7q) combined with monosomy 7 and deletions or translocations involving part of 7q. The prognostic significance of the cytogenetic changes requires prospective monitoring for clarification. Of the patients with i(7q), progression to MDS with excess blasts or to AML has rarely been reported. Similarly, SDS patients with del(20q) rarely evolve into MDS/AML. In a prospective 5-year follow-up Canadian study of SDS patients, progression to overt transformation was not seen in two patients with del(20q), one patient with i(7q), and one with combined del (20q) and i(7q). Similarly, no progression was seen in six additional patients with i(7q) from several hospitals in the United Kingdom. In contrast, approximately 40% of patients with the other chromosomal 7 abnormalities progress to either advanced MDS or to AML.

The pathophysiologic link between *SBDS* mutations and propensity to MDS and AML is unknown. It is possible that patients with SDS cells develop more frequent mutations caused by genomic instability possibly because of mitotic spindle dysregulation or telomere shortening. It is also possible that impaired ribosome biogenesis and accelerated apoptosis cause a growth disadvantage for SDS BM cells, allowing for a growth advantage and expansion of malignant clones. Although molecular and cellular parameters do not distinguish SDS patients with transformation from SDS patients without transformation, it is remarkable that all SDS BM demonstrates many characteristic features observed in MDS. These include impaired BM stromal support of normal hematopoiesis, increased BM cell apoptosis mediated by the Fas pathway, telomere shortening of leukocytes, increased BM neovascularization, high frequency of clonal cytogenetic abnormalities, and abnormal leukemia-related gene expression in BM progenitor cells.

The vast majority of the published cases of SDS-associated MDS/AML developed without previous G-CSF therapy. None of the six patients with SDS-associated MDS/AML from our institution were treated with G-CSF before transformation. However, it is still unclear whether G-CSF increases the risk of developing leukemia or promotes the expansion of existing malignant clones. Because G-CSF might increase neutrophil counts and prevent infections in SDS, a fraction of the reported patients with SDS-associated MDS/AML had been previously treated with G-CSF. For example, two of the 29 SDS patients on the Severe Chronic Neutropenic International Registry who received G-CSF therapy developed MDS/leukemia.

Shwachman-Bodian-Diamond syndrome must play a critical role in preventing leukemic myeloid transformation because up to one-third of SDS patients develop MDS/AML. To address whether an acquired mutant *SBS* gene is associated with leukemic transformation in de novo AML, 77 AML BM samples at diagnosis or relapse were analyzed for *SBS* mutations, and none were identified. To see

if a subset of previously undiagnosed SDS patients presented for the first time with AML, 48 AML BM samples were studied at remission, but no *SBDS* mutations were found. SDS patients with MDS/AML have common *SBDS* mutations, and a genotype–phenotype study of 21 patients with SDS with MDS/AML showed no relationship (Linda Ellis, RN, Toronto, personal communication). Thus, the link between mutant SBDS; hematologic cancer; and upregulated oncogenes, including *LARG,* and *TAL1,* is undetermined.

Differential Diagnosis

The introduction of genetic testing has improved the ability to diagnose the disorder and particularly has helped identify cases with an atypical presentation (Y. Dror, unpublished data). The diagnostic criteria include having at least two of the following: (1) chronic BM failure, (2) exocrine pancreatic insufficiency, (3) positive genetic testing results, and (4) a first degree-relative with SDS.

The syndrome of refractory sideroblastic anemia with vacuolization of BM precursors, or **Pearson syndrome,** is clinically similar to SDS but characterized by very different BM morphology. Severe anemia requiring transfusions rather than neutropenia is often present at birth and by 1 year of age in all cases. In contrast to SDS, the major BM morphologic findings are ringed sideroblasts with decreased erythroblasts and prominent vacuolation of erythroid and myeloid precursors. The disorder shares clinical similarities with SDS because of exocrine pancreatic dysfunction. Malabsorption and severe failure to thrive occur in approximately half of cases within the first 12 months of life. Qualitative pancreatic function tests show depressed acinar function and reduced fluid and electrolyte secretion. Approximately 50% of reported patients die early in life from sepsis, acidosis, and liver failure; the others appear to improve spontaneously with reduced transfusion requirements. At autopsy, the pancreas shows acinar cell atrophy and fibrosis; fatty infiltration as seen in SDS is not a prominent feature. The need for long-term pancreatic enzyme replacement is unclear. These patients have a diagnostic deletion of mitochondrial deoxyribonucleic acid (mtDNA). mtDNA encodes enzymes in the mitochondrial respiratory chain that are relevant to oxidative phosphorylation, including the reduced form of nicotinamide adenine dinucleotide dehydrogenase (NADH), cytochrome oxidase, adenosine triphosphatase (ATPase), transfer ribonucleic acids (tRNAs), and ribosomal RNAs. The degree of heteroplasmy affects the disease expression. Transplantation of mouse BM cells carrying mitochondrial DNA with a large-scale deletion into normal mice leads to macrocytic anemia in mice with hematopoietic cells carrying a high proportion of abnormal mitochondria. The deletion impairs erythroid differentiation and erythropoietic response to stress.

Shwachman-Diamond syndrome shares some manifestations with **FA** such as BM dysfunction and growth failure, but patients with SDS can usually be distinguished because of malabsorption syndrome, fatty changes within the pancreatic body that can be visualized by imaging, and characteristic skeletal abnormalities not seen in patients with FA. In difficult cases with incomplete disease expression, the distinction relies on normal clastogenic stress-induced chromosome fragility testing and genetic testing. Mutational analysis for mutant *SBDS* is definitive, but 10% of classic clinical SDS do not have a mutant *SBDS*.

Atypical SDS cases with only little evidence of pancreatic changes can be difficult to distinguish from early-onset **dyskeratosis congenita** with no mucocutaneous manifestations. Establishing a diagnosis in such cases can be assisted by telomere length screening, which might show telomere shortening but typically not in the very severe range seen in dyskeratosis congenita.

Prognosis

Because of the broad pleiotropy in SDS, the number of undiagnosed patients with mild or asymptomatic disease is unknown. Hence, the overall prognosis may be better than previously thought. The majority of *SBDS* mutations represent hypomorphic alleles with reduced but variable protein expression. Also, there is phenotypic heterogeneity in patients carrying identical *SBDS* mutations. Therefore, until more information is forthcoming, the natural history and prognosis are not yet defined.

From a literature review, the projected median survival of SDS patients was calculated as 35 years. During infancy, morbidity and mortality are mostly related to malabsorption, infections, and thoracic dystrophy. Later in life, the major problems are hematologic or complications related to their treatment. Cytopenias tend to fluctuate in severity but do not fully resolve spontaneously. The most common cause of death in late childhood or adulthood is related to MDS/AML.

Therapy

Patient management is ideally shared by a multidisciplinary team consisting of a hematologist and a gastroenterologist as core members and other subspecialists such as a dentist and a psychologist as required. The malabsorption component of SDS responds to treatment with oral pancreatic enzyme replacement with meals and snacks using guidelines similar to those for cystic fibrosis. Supplemental fat-soluble vitamins are also usually required. When monitored over time, approximately 50% of patients convert from pancreatic insufficiency to sufficiency because of spontaneous improvement in pancreatic enzyme secretion. This improvement is particularly evident after 4 years of age. A long-term plan should be initiated for early detection of severe cytopenias that require corrective action or malignant myeloid transformation. There are currently no data about the cost effectiveness of a specific leukemia surveillance program in SDS. However, it is generally accepted that it should include periodic blood counts with differentials and blood smears every 3 to 4 months, a clinical evaluation by a hematologist every 6 months, and BM testing every 1 to 3 years. The latter includes aspirates for smears and cytogenetics analyses. Concomitant BM biopsies are recommended when the patient's clinical status changes.

G-CSF

G-CSF given for profound neutropenia has been very effective in inducing a clinically beneficial neutrophil response. Of 16 SDS patients in the Severe Chronic Neutropenia International Registry (SCNIR) treated with G-CSF, 14 had brisk neutrophil responses that were sustained in some cases for more than 11 years (Beate Schwinzer, Hannover, Germany, personal communication).

Steroids and Androgens

A small number of patients have been treated with corticosteroids with hematologic improvement in 50%. A smaller number received androgens plus steroids in the manner of treating FA, and improved BM function was also noted. Anecdotal cases treated with androgens alone, cyclosporine, or erythropoietin do not allow broad therapeutic conclusions.

Blood Products and Other Supportive Care

Anemia and thrombocytopenia are managed with transfusions of RBCs or platelets when symptoms appear or prophylactically for profound cytopenias. Antifibrinolytic therapy with tranexamic acid can also be given for mild mucosal bleeding. Broad-spectrum antibiotics are indicated for febrile episodes and severe neutropenia.

Hematopoietic Stem Cell Transplantation

At present, the only curative option for severe BM failure in SDS is allogeneic HSCT. The indications for HSCT include BM failure with severe or symptomatic cytopenia, MDS with excess blasts (5%-29%),

or leukemia. Published data are limited and derived from case reports or small case series with a mix of sibling and matched unrelated donors. Two registries in Europe have provided additional information.

The European Group for Blood and Bone Marrow Transplantation (EBMT) Registry reported 26 transplanted SDS patients. The indications included aplastic anemia ($n = 16$), MDS/AML ($n = 9$), or other ($n = 1$). Patients were transplanted with myeloablative conditioning regimens that included either busulfan or total-body irradiation. The majority of the donors were unrelated ($n = 19$). Eighty-one percent engrafted. The incidence of grade III to IV GVHD was 24%; chronic GVHD was 29%. The overall survival was 65% at 1.1 years. Deaths were primarily caused by infections, GVHD, or major organ toxicities. Factors associated with adverse outcome included MDS/AML or usage of total-body irradiation.

The French Neutropenia Registry reported 10 transplanted SDS patients. The indications included severe BM failure ($n = 5$) or MDS/leukemia ($n = 5$). Patients were conditioned with myeloablative regimens incorporating busulfan or total-body irradiation. Six received grafts from unrelated donors and four from a sibling donor. BM engraftment occurred in eight patients. The 5-year overall survival was 60%. Causes of death included infections related to neutropenia, GVHD, relapse, and transplant-related toxicity. Factors associated with adverse outcome included MDS/AML.

A note of caution is sounded regarding HSCT for SDS. Left ventricular fibrosis and necrosis without coronary arterial lesions have been reported in 50% of SDS patients at autopsy, suggesting that there may be an increased risk of cardiotoxicity as well as other problems with the intensive preparatory chemotherapy used in HSCT. Indeed, published data emphasized that complications are more common in SDS patients who receive chemotherapy or undergo transplantation than in non-SDS patients with aplastic anemia. Complications include cardiotoxicity, neurologic and renal complications, venoocclusive disease, pulmonary disease, posttransplant graft failure, and severe GVHD. The heightened risk for patients with SDS after transplantation can be explained in three ways; (1) the presence of the SDS BM stromal defect that is not corrected by the allograft and might be aggravated by the conditioning regimen; (2) increased sensitivity to chemotherapy and radiation, resulting in massive apoptosis in various organs; or (3) performing HSCT relatively late and at an advanced disease stage.

Results of reduced intensity HSCT regimens have been published by two groups. In a study from Cincinnati published in 2008, six patients with severe cytopenia with or without clonal BM cytogenetic abnormalities and one patient with AML in remission were transplanted. The conditioning regimen included Campath-1H, fludarabine, and melphalan. Four patients received matched related MB, two received unrelated peripheral blood, and one had unrelated BM. All patients engrafted and were alive at a median follow-up of 548 (range, 93-920) days. In another study from Hannover, three patients received conditioning with fludarabine, treosulfan, and melphalan in addition to Campath-1H or rabbit ATG. Donor sources were matched sibling BM, matched unrelated BM, or 9/10 matched cord blood. The indications were severe BM failure ($n = 2$) and MDS ($n = 1$). The patients who received BM cells survived at 9 and 20 months posttransplant. The other patient died of idiopathic pneumonitis.

Future Directions

Mutant *SBDS* causes SDS in 90% of clinically diagnosed patients. The hunt for additional causative mutant genes in the other 10% is still underway. Identification of such gene(s) may expand our understanding of pathogenesis. Several other clinical and basic research questions in SDS must be addressed. First, the various biochemical functions of the *SBDS* gene require further study. How SBDS protein maintains normal hematopoiesis and protects from apoptosis as well as cancer is unclear. The complete clinical phenotype, natural history, and risk factors for the development of complications need to be determined. There is also a need to understand the mechanism for the heightened sensitivity of SDS patients to chemotherapy and irradiation and to develop low-intensity regimens for HSCT. Research should continue on the efficacy of innovative drugs such as antiapoptotic agents in increasing the growth potential of HSCs and relieving the severity of cytopenia. Determining risk factors and molecular events during malignant myeloid transformation might prompt strategies for prevention and screening for complications.

Dyskeratosis Congenita

Background

Dyskeratosis congenita is an inherited multisystem disorder of the mucocutaneous and hematopoietic systems in association with a wide variety of other somatic abnormalities. Originally, it was considered a dermatologic disease and was termed *Zinsser-Cole-Engman syndrome*. The traditional diagnostic ectodermal triad consists of reticulate skin pigmentation of the upper body, mucosal leukoplakia, and nail dystrophy. The skin and nail findings usually become apparent during the first 10 years of life, but the oral leukoplakia is observed later. These manifestations tend to progress as patients get older.

Hematologic manifestations were subsequently recognized to be a major component of the syndrome and are responsible for substantial morbidity and mortality. Indeed, the full diagnostic dermatologic triad is present only in about 46% of the patients, but BM failure of varying severity is reported in up to 90% of cases. With the recent advances in understanding the molecular basis of the disease, patients with hematologic abnormalities but without dermatologic findings have been identified that dramatically changed the historical definition of the disease. Dyskeratosis congenita patients also have a predisposition to develop cancer and MDS.

Epidemiology

About 550 cases have been reported in the literature. The incidence of dyskeratosis congenita in childhood is about 4 cases per million per year. In older literature, most DC patients were reported as males. However, with better understanding and broadening of the clinical spectrum of the disease and with more autosomal cases being identified, the proportion of males is much lower.

Pathobiology

Multiple genes have been associated with DC (see Table 27-1). All are components of the telomerase complex or the shelterin protein complex. The **X-linked recessive** disease is a common form of DC. It was originally estimated to comprise as many as 75% of DC cases, but with the identification of more DC genes and more patients with autosomal dominant inheritance, the true incidence is approximately 30%. The X-linked disease is caused by mutations in *DKC1* on chromosome Xq28. *DKC1* encodes for the protein dyskerin. Dyskerin associates with the H/ACA class of RNA. Dyskerin binds to the 3′ H/ACA small nucleolar RNA-like domain of the *TERC* component of telomerase. This stimulates telomerase to synthesize telomeric repeats during DNA replication. Dyskerin is also involved in maturation of nascent rRNA. It binds to small nucleolar RNA through the 3′ H/ACA domain and catalyzes the isomerization of uridine to pseudouridine through its peudouridine synthase homology domain. This might be the mechanism for impaired translation from internal ribosome entry sites seen in mice and human DC cells.

Several genes are mutated in families with **autosomal dominant** inheritance. *TINF2* is probably the most commonly mutated gene in this group and accounts for approximately 11% to 25% of the DC families. TINF2 protein is part of the shelterin protein complex that binds to and protects telomeres by allowing cells to distinguish between telomeres and regions of DNA damage. In the complex, TINF2 binds to TRF1, TRF2, POT1, TPP1, and RAP1.

Heterozygous mutations in *TERT* also results in autosomal dominant disease. *TERT* encodes for the enzyme component of telomerase. Telomerase is a ribonucleoprotein polymerase that maintains telomere ends by synthesis and addition of the telomere repeat TTAGGG at the 3′-hydroxy DNA terminus using the *TERC* RNA as a template.

Heterozygous mutations in the *TERC* gene are another cause of autosomal dominant DC. *TERC* encodes for the RNA component of telomerase and has a 3′ H/ACA small nucleolar RNA -like domain.

The **autosomal recessive** forms of DC are caused by biallelic mutations in *NOP10*, *NHP2, TERT,* or *TCAB1*. In the telomerase complex, the H/ACA domain of nascent human telomerase RNA forms a pre-ribonucleoprotein with NAF1, dyskerin, NOP10, and NHP2. Initially, the core trimer dyskerin-NOP10-NHP2 forms to enable incorporation of NAF1, and efficient reverse transcription of telomere repeats. NOP10 and NHP2 also play an essential role in the assembly and activity of the H/ACA class of small nucleolar ribonucleoproteins that catalyze the isomerization of uridine to pseudouridine in rRNAs.

TCAB1 facilitates trafficking of telomerase to Cajal bodies. Mutations in this gene impair this trafficking activity and lead to misdirection of telomerase RNA to nucleoli; thereby preventing elongation of telomeres by telomerase.

Dyskeratosis congenita cells are characterized by very short telomeres. In several acquired and inherited BM failure syndromes, telomeres are short compared with those from age-matched control participants. However, because the telomerase function is profoundly impaired in DC, the telomeres in this disease are very short (lower than the first percentile of the normal range). Shortening of telomeres results in cellular senescence, apoptosis ("cellular crisis"), or chromosome instability. However, some cells may survive the crisis by harboring compensatory genetic mutations that confer proliferative advantage and neoplastic potential.

Dyskeratosis congenita is a chromosome "instability" disorder of a different type than FA. Results of clastogenic stress studies of DC cells are normal. There is no significant difference in chromosomal breakage between patient and normal lymphocytes with or without exposure to bleomycin, DEB, MMC, or γ-radiation. This contrasts sharply with FA cells and distinguishes one disorder from the other. However, metaphases of cultured patient peripheral blood cells, BM cells, and fibroblasts show numerous spontaneous unbalanced chromosome rearrangements such as dicentrics, tricentrics, and translocations. These are probably caused by short telomeres.

Dyskeratosis congenita with mutations in the *DKC1* (X-linked recessive DC) or *TINF2* and biallelic *TERT* mutations (autosomal recessive DC) can result in a severe form of DC called **Hoyeraal Hreidarsson syndrome**. It is characterized by hematologic and dermatologic manifestations of DC in addition to cerebellar hypoplasia. Immune deficiency is common when this syndrome is caused by *DKC1* mutations. **Revez syndrome** is a combination of classical manifestations of DC and exudative retinopathy. It is caused by mutations in *TINF2* and is an autosomal dominant form of the disease. *TINF2* mutations have also been in children with severe **aplastic anemia** without physical anomalies. Biallelic mutations in *TERT* are also associated with a severe form of DC. However, heterozygosity for mutations in *TERT* is associated with a milder phenotype, late presentation, severe aplastic anemia without physical malformations, isolated pulmonary fibrosis, isolated hepatic fibrosis, or a combination of these clinical manifestations. Heterozygosity for mutations in *TERC* is associated with a milder phenotype, late presentation and severe aplastic anemia, or MDS without physical malformations.

Most studies of the pathogenesis of the aplastic anemia in DC have shown a marked reduction or absence of CFU-GEMM, BFU-E, CFU-E, and CFU-GM. Long-term DC BM cultures have shown that hematopoiesis is severely defective in all patients with a low frequency of colony-forming cells. The function of DC BM stromal cells is normal in their ability to support growth of hematopoietic progenitors from normal BM, but generation of progenitors from DC BM cells seeded over normal stroma is reduced, suggesting that the defect in DC is of stem cell origin. Telomerase is activated in HSCs; however, how mutations that impair telomere maintenance disrupt hematopoiesis is unclear. The BM failure in this disorder may be a result of a progressive attrition and depletion of HSCs. Alternatively, the BM dysfunction may represent a failure of replication, maturation, or both.

Induced pluripotent stem cells (iPSCs) from dyskeratosis congenita patients have been shown to have defects in telomere elongation during programming in a mechanism that is concordant with the mutated gene in the patients. In iPSCs from patients with heterozygous mutations in *TERT,* telomerase activity is directly affected. iPSCs from patients with mutant *DKC1* manifest reduced telomerase activity because of impaired telomerase assembly. iPSCs from a patient with *TCAB1* mutations are characterized mislocalization of telomerase from Cajal bodies to nucleoli. It was also shown that extended culture of *DKC1*-mutant iPSCs leads to progressive telomere shortening and eventual loss of self-renewal. In contrast, another group studied telomerase reactivation and *TERC* regulation during reprogramming and showed that reprogramming restores telomere elongation in dyskeratosis congenita cells despite genetic lesions affecting telomerase. This group showed that *TERC* upregulation is a feature of the pluripotent state and that several telomerase components are targeted by pluripotency associated transcription factors.

Clinical Features

Clinical manifestations in dyskeratosis congenita often appear during childhood. The skin pigmentation and nail changes typically appear first; mucosal leukoplakia and excessive ocular tearing appear later; and by the mid-teens, the serious complications of BM failure and malignancy begin to develop. In a portion of the patients, BM abnormalities appear before or without the skin manifestations.

The DC Registry data from England have detailed the prevalence of somatic abnormalities in families with classic DC. Cutaneous findings are a typical feature of the syndrome. Lacy reticulated skin pigmentation affecting the face, neck, chest, and arms is a common finding (89%). The degree of pigmentation increases with age and can involve the entire skin surface. There may also be a telangiectatic erythematous component. Nail dystrophy of the hands and feet is the next most common finding (88%) (Fig. 27-4). It usually starts with longitudinal ridging, splitting, or pterygium formation and may progress to complete nail loss. Leukoplakia usually involves the oral mucosa (78%), especially the tongue (Fig. 27-5), but may also be seen in the conjunctiva, anal, urethral, or genital mucosa. Hyperhidrosis of the palms and soles is common, and hair loss is sometimes seen. Eye abnormalities are observed in approximately 50% of cases. Excessive tearing (epiphora) secondary to nasolacrimal duct obstruction is common. Other ophthalmologic manifestations include conjunctivitis, blepharitis, loss of eyelashes, strabismus, and cataracts and optic atrophy. Abnormalities of the teeth, particularly an increased rate of dental decay and early loss of teeth, are common. Skeletal abnormalities such as osteoporosis with recurrent long bone fractures, avascular necrosis, abnormal bone trabeculation, scoliosis, and mandibular hypoplasia are seen in approximately 20% of cases. Genitourinary abnormalities include hypoplastic testes, hypospadias, phimosis, and urethral stenosis and horseshoe kidney. Gastrointestinal findings, such as esophageal strictures, hepatomegaly, or cirrhosis, are seen in 10% of cases. A subset of patients develops idiopathic pulmonary fibrosis with reduced diffusion capacity or a restrictive defect. In fatal cases, lung tissue shows pulmonary fibrosis and abnormalities of the pulmonary vasculature. Hepatic fibrosis may also occur. Vasculopathy of the gut, kidneys, liver, chest, or other organs is seen in severe cases and may cause massive bleeding.

Laboratory Findings

Peripheral Blood, Bone Marrow, and Immunologic Findings

The incidence of cytopenias caused by BM failure has been reported in up to 90% of the patients. Severe aplastic anemia occurs in about

Figure 27-4 DYSTROPHIC NAILS IN DYSKERATOSIS CONGENITA.

Figure 27-5 LEUKOPLAKIA OF THE TONGUE IN DYSKERATOSIS CONGENITA.

50% of the patients. When BM failure is evident, most patients already have physical manifestations of DC, but this is variable. The initial hematologic change is usually thrombocytopenia, anemia, or both followed by full-blown pancytopenia caused by aplastic anemia. The RBCs are often macrocytic, and the fetal hemoglobin can be elevated. In is noteworthy that early BM specimens and biopsies may be normocellular or hypercellular; however, with time, the cellular elements decline with a symmetrical decrease in all hematopoietic lineages. Ferrokinetic studies at this point are consistent with aplastic anemia. Some patients with DC, particularly those with *DKC1* mutations, have immunologic abnormalities, including reduced immunoglobulin levels, reduced B- or T-lymphocyte numbers, and reduced or absent proliferative responses to PHA. Severe immunodeficiency necessitating HSCT has also been described.

On imaging studies, a small-sized cerebellum may give a clue to the diagnosis in patients with atypical presentations. Imaging of the skeleton usually shows nonspecific osteopenia.

Telomere length is a useful screening testing for DC. In the vast majority of patients, the telomeres are very short (i.e., lower than the first percentile adjusted to age).

Cancer Predisposition

Cancer develops in about 10% to 15% of patients, usually in the third and fourth decades of life. Similar to FA, DC patients can develop solid tumors as well as MDS/AML. However, the incidence of MDS/AML in DC is much lower than in FA. At the age of 50 years, the cumulative risk of solid cancers and MDS/AML is estimated as 40% and 3%, respectively. Most of the cancers are squamous cell carcinomas or adenocarcinomas, and the oropharynx and gastrointestinal tract are involved most frequently. Some patients have multiple separate primaries in different sites involving the tongue and nasopharynx. Thus, the sites of most of the cancers involve areas known to be abnormal in DC, such as mucous membranes and the gastrointestinal tract.

Differential Diagnosis

Several physical findings can be used to distinguish **FA** from DC. The following abnormalities are seen only in DC and not FA: nail dystrophy, leukoplakia, abnormalities of the teeth, hyperhidrosis of the

palms and soles, and hair loss. There are overlap syndromes that share some of the features of DC. The **Hoyeraal-Hreidarsson syndrome** variant of DC and the **Revesz syndrome** variant of DC are two examples. Mutant *TINF2* was identified in Revesz syndrome and hence is an autosomal dominant variant of DC. **The ataxia–pancytopenia syndrome** at least in some families is a variant of DC with mutations in *TINF2*.

Natural History and Prognosis

In classical DC, nail dystrophy and skin pigmentation present first, often in the first 10 years of life. BM failure usually follows in the teenage years and twenties. The primary causes of death are hemorrhage secondary to thrombocytopenia or intestinal vascular anomalies, sepsis from severe neutropenia, and complications after HSCT. In the patients who develop cancer or MDS, the disease or its treatment can prove fatal. Pulmonary fibrosis can develop in 20% of cases and is typically progressive and culminates in death caused by respiratory failure. Considerable clinical heterogeneity exists even within the same family, and some patients live into their forties with only moderate nail changes and mild cytopenias. The median survival in the cases reported in the past decade was estimated at 49 years.

Therapy

Androgens

Management of aplastic anemia is similar to treatment for FA. Androgens improve BM function in about 50% of patients. If a response is achieved and deemed to be maximal, the androgen dose can be slowly tapered but not stopped. As in FA, patients typically become refractory to androgens as aplastic anemia progresses. Immunosuppressive therapy is not effective for this disorder, and a portion of the patients with DC are only diagnosed after failure to respond to immunosuppressive therapy for severe aplastic anemia.

G-CSF

A small number of patients were reported who responded to G-CSF therapy with significant increases in absolute neutrophil counts (ANCs). Similarly, two other patients received GM-CSF therapy that resulted in improved neutrophil numbers. G-CSF with erythropoietin resulted in a trilineage hematologic response in one patient. G-CSF plus androgens has led to splenic peliosis and rupture in DC and is not recommended as a long-term treatment if a donor for HSCT is available. Although the reports are scanty, cytokine therapy appears to offer potential benefit, at least in the short term, especially for improving granulopoiesis.

Hematopoietic Stem Cell Transplantation

The outcomes of about 70 patients with DC who have undergone HSCT have been reported. However, the publications are mostly isolated case reports or a small series that limit one's ability to make meaningful correlations of the types of regimens, donors, and indications with outcome. The older literature consists of patients who received myeloablative regimens resulting in a median survival of approximately 3 years after HSCT. Causes of death include unusual complications related to DC that are not prevented by HSCT such as vascular lesions of the gut, kidneys, liver, and lung (≈50% of the patients) and fibrosis involving the lung and liver (≤40% of the patients). These striking complications after HSCT probably reflect the natural history of the disease. However, it is not known whether HSCT can accelerate their course. These unusual complications, uniquely seen in DC, have not been reported in other inherited BM failure syndromes such as FA.

Dyskeratosis congenita is a disorder with chromosomal instability caused by flawed telomere maintenance. This might explain the hypersensitivity to irradiation and chemotherapy. The increased hypersensitivity of DC patients to transplant conditioning can be related to the telomere shortening from DC combined with the accelerated telomere shortening that occurs after HSCT. Further, because of the high degree of mucocutaneous involvement, DC patients may be more susceptible to endothelial damage, which occurs after HSCT as a result of various factors, including the conditioning regimen, cyclosporine A, infectious diseases, GVHD, and cytokine storm. The increased predisposition to posttransplant complications and the tendency to develop tumors highlight the need to avoid certain conditioning agents such as busulfan and irradiation and possibly reduce the intensity of the transplant preparative regiments.

The strategy of using low-intensity fludarabine-based protocols for HSCT has produced encouraging results for DC patients. From 2002 to 2011, 14 patients were transplanted using fludarabine-based reduced intensity protocols. Overall, 11 of the 14 were reported alive at 10 to 72 months posttransplant. These regimens appear to be well tolerated and allow prompt engraftment without significant complications. However, the benefit in reducing the risk of disease-related complications, such as bleeding from vascular lesions and respiratory failure caused by pulmonary fibrosis, is not clear. A Toronto patient reported in 2003 did develop these two complications 7 years after transplant. Also, the role of these conditioning regimens in increasing the additive risk of cancer caused by HSCT is still to be determined.

Future Directions

Although six mutated genes for the three forms of DC have been identified, only 50% of the patients can now be genotyped. Clearly, there is a need to discover additional DC genes. Furthermore, the mechanism by which impaired activity, transport, and stability of telomerase and other ribonucleoprotein complexes influence HSC function requires clarification. Effective therapies with reduced toxicity are necessary to prevent devastating complications such as BM failure, pulmonary fibrosis, and vascular anomalies. Last, there is a need for studies focusing on translating this genetic knowledge into gene therapy.

Congenital Amegakaryocytic Thrombocytopenia

Background

Congenital amegakaryocytic thrombocytopenia (CAMT) is an autosomal recessive syndrome that typically presents in infancy with isolated thrombocytopenia caused by reduced or absent BM megakaryocytes with preservation initially of granulopoietic and erythroid lineages (see Chapters 26). Aplastic anemia subsequently ensues in the vast majority of the patients, usually in the first few years of life. Most patients do not have physical malformations; therefore, the diagnosis depends on the exclusion of other acquired and inherited causes of thrombocytopenia in early life. Mutations of the thrombopoietin receptor, MPL, have been identified and confirm that sporadic and familial cases are inherited in an autosomal recessive manner. *CAMT* is a distinct genetic entity, but mutations in several other genes have been described in a number of inherited thrombocytopenias that must be considered in the differential diagnosis (Table 27-5).

Epidemiology

More than 100 cases have been reported in the literature. However, with the recent identification of patients with *MPL* mutations and relatively late presentation, it is possible that the incidence is higher and includes a portion of the patients with aplastic anemia who do not respond to immunosuppressive therapy. The incidence of diagnosed cases is estimated at one case per million births per year.

Table 27-5 Miscellaneous Inherited Thrombocytopenia Disorders and Their Major Hematologic Features

Disorder	Genetics	Mutant Gene	Platelet Size*	Features
Amegakaryocytic thrombocytopenia	AR	*MPL*	Normal	± Physical anomalies
Thrombocytopenia absent radii	AR	Unknown	Normal	Physical anomalies
MYH9-related thrombocytopenia: May-Hegglin anomaly	AD	*MYH9*	Large	Neutrophil inclusions
Fechtner syndrome	AD	*MYH9*	Large	Neutrophil inclusions, hearing loss, nephritis
Epstein syndrome	AD	*MYH9*	Large	No inclusions, hearing loss, nephritis
Sebastian syndrome	AD	*MYH9*	Large	Neutrophil inclusions
X-linked macrothrombocytopenia	X-L	*GATA1*	Large	Anemia, dyserythropoiesis, thalassemia
Wiskott-Aldrich syndrome	X-L	*WAS*	Small	Immune deficiency, eczema
X-linked thrombocytopenia	X-L	*WAS*	Small	No associated features
Thrombocytopenia and radio-ulnar synostosis	AD	*HOXA11*	Normal	Fused radius, limited range of motion
Familial platelet disorder/AML	AD	*AML1 (RUNX1; CBFA2)*	Normal	MDS, AML
Familial dominant thrombocytopenia	AD	*FLJ14813*	Normal	No associated features
Paris-Trousseau thrombocytopenia	AD	*FLI1* (hemizygous deletion)	Large	Dysmegakaryocytopoiesis, Jacobsen syndrome
Bernard-Soulier syndrome	AR	*GP1BA*	Large	No associated features
Bernard-Soulier carrier/Mediterranean macrothrombocytopenia	AD	*GP1BA*	Large	No associated features

AD, Autosomal dominant; *AML,* acute myeloid leukemia; *AR,* autosomal recessive; *MDS,* myelodysplastic syndrome; *MPV,* mean platelet volume; *X-L,* X-linked recessive.
*Platelet size: small, MPV <7 fL; normal, MPV 7-11 fL; large or giant, MPV >11 fL.

Pathobiology

The defect in CAMT is directly related to mutations in *MPL,* the gene for the thrombopoietin receptor that maps to 1p34 in 94% of the patients. Heterozygote carriers of the mutant gene have normal blood cell counts. Affected individuals have mutations in both alleles in either homozygous or compound heterozygous state. Mutations have been found throughout the *MPL* gene, including nonsense, missense, frameshift, and splicing mutations. A genotype–phenotype correlation has been identified in CAMT patients and two prognostic groups established, types I and II.

Type 1

Frameshift and nonsense mutations produce a complete loss of function of and signaling from the thrombopoietin receptor in type I by deletion of all or most of the intracellular domain. This causes persistently low platelet counts and a rapid progression to pancytopenia. Thrombopoietin plays a critical role in the proliferation, survival, and differentiation of early and late megakaryocytes. This clearly explains the thrombocytopenia. However, *MPL* is also highly expressed in HSCs and promotes their quiescence and survival. Thus, MPL protein insufficiency may account for depletion of HSCs and pancytopenia. Evolution into severe aplastic anemia is particularly common in type I.

Type II

Congenital amegakaryocytic thrombocytopenia with missense and splicing mutations cause reduced expression of the protein, reduced localization to the plasma membrane (e.g., R102P in the extracellular domain), or an inability to bind thrombopoietin (e.g., F104S). Patients with these mutations have a milder course; a transient increase in platelet counts during the first years of life; and delayed onset, if any, of pancytopenia, indicating residual receptor function.

Serial studies of CAMT hematopoiesis using clonogenic assays have been informative. Initially, when the only hematologic abnormality is isolated thrombocytopenia, the numbers of hematopoietic progenitors are comparable to those of control participants, including the number of megakaryocyte precursors, CFU-MK (colony-forming unit megakaryocytes; CFU-Meg). As the disease evolves into aplastic anemia, the peripheral blood counts decline, and colony numbers from progenitors belonging to each myeloid lineage also decline in parallel. When added to the BM cultures, patient plasma is not inhibitory to control or to patient colony growth. Similarly, no cellular inhibition of hematopoiesis is observed when the patient BM is cultured after depleting the sample of T lymphocytes or after adding them back. Stromal cells established in short- and long-term cultures of patient BM show normal proliferative activity and yield a "fertile" BM microenvironment for patient and control BM colony growth. The findings are consistent with current knowledge about *MPL* mutations, namely, that the central problem in CAMT is an intrinsic HSC defect rather than an abnormality of the BM milieu.

Other data demonstrate measurable numbers of CFU-MK progenitors in vitro from patients with CAMT when studied early in the disease in response to IL-3, GM-CSF, or a combination of both but defective CFU-MK colony formation in response to recombinant human thrombopoietin that fits with *MPL* mutations. Plasma thrombopoietin levels in patients with CAMT are always elevated and are among the highest seen in any patient population.

The pathogenesis of the associated neurologic abnormalities (see Clinical Features) is less understood; however, MPL is expressed in the neuronal cells and might be important for their development.

Clinical Features

Almost all patients present with a petechial rash, bruising, or bleeding during the first year of life. Most cases are obvious at birth or within the first 2 months. Almost all of the patients with proven *MPL* mutations have normal physical and imaging features, but isolated cases with anomalies have been identified. A patient in the Canadian Registry with an *MPL* mutation had a cystic fourth ventricle and Dandy Walker malformation (unpublished data).

Before the availability of genotyping, physical anomalies were an important part of the clinical phenotype in published case reports and small series. The commonest anomalies in published phenotypic CAMT patients are neurologic, including varying degrees of cerebellar hypoplasia or agenesis, cerebral atrophy, cortical dysplasia and lissencephaly, and hypoplasia of the corpus callosum and brainstem. Facial malformations have also been described. Developmental delay is a prominent feature among those with physical malformations. Patients may also have microcephaly and an abnormal facies.

Congenital heart disease with a variety of malformations can be detected, including atrial septal defects, ventricular septal defects, patent ductus arteriosus, tetralogy of Fallot, and coarctation of the aorta. Some of these occur in combinations. Other anomalies include abnormal hips or feet, kidney malformations, eye anomalies, and cleft or high-arched palate. Some affected sibships manifested both normal and abnormal physical findings in the same family.

Laboratory Findings

Thrombocytopenia is the major laboratory finding with normal hemoglobin levels and white blood cell counts initially. Although there are usually measurable but reduced platelet numbers, peripheral blood platelets may be totally absent. Those that can be identified are of normal size and appearance. Similar to other inherited BM failure syndromes, RBCs may be macrocytic. HbF is increased in most but not all patients, and there may be increased expression of i antigen. BM aspirates and biopsies initially show normal cellularity with markedly reduced or absent megakaryocytes (Fig. 27-6). In patients who develop aplastic anemia, BM cellularity is decreased with fatty replacement, and the erythropoietic and granulopoietic lineages are symmetrically reduced.

Predisposition to Leukemia

Cases with CAMT have been reported with secondary clonal BM cytogenetic abnormalities such as monosomy 7 and trisomy 8, MDS, or AML. Several published cases clearly demonstrate a typical progression of thrombocytopenia, aplastic anemia, and clonal or malignant myeloid transformation. One boy with a normal physical appearance had amegakaryocytic thrombocytopenia from day 1 of life, developed aplastic anemia at 5 years of age, responded poorly to androgens and steroids, and then developed AML at age 16 years with death at age 17 years. A girl had thrombocytopenia at 2 months of age, pancytopenia at 5 months, and thereafter developed a preleukemic picture with clonal abnormalities involving chromosome 19. Another patient had thrombocytopenia at 6 months of age, developed progressive aplastic anemia over the next 2 years, acquired monosomy 7 in BM cells at 5 years of age, and then developed MDS with an activating *RAS* oncogene mutation in hematopoietic cells. Hence, the current evidence indicates that CAMT is another inherited BM failure disorder that is preleukemic. The risk or incidence of malignant conversion is difficult to determine because of the rarity of the disease and the paucity of published data, and because patients frequently require early HSCT.

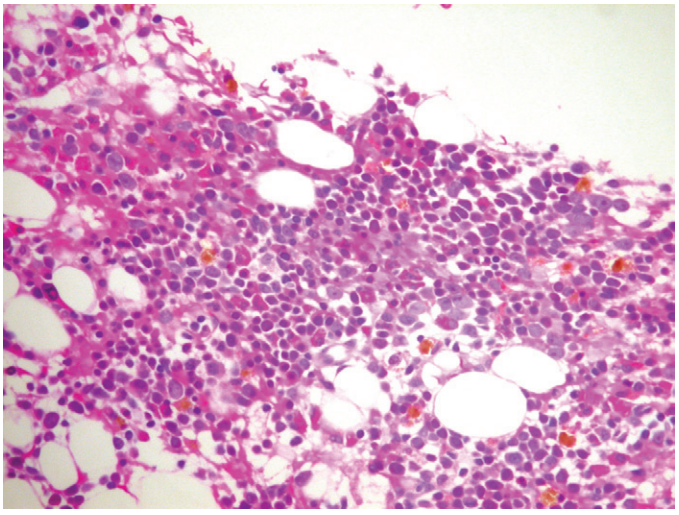

Figure 27-6 LOW-POWER VIEW OF A BONE MARROW ASPIRATE FROM A NEWLY DIAGNOSED PATIENT WITH CONGENITAL AMEGAKARYOCYTIC THROMBOCYTOPENIA. The three findings are normal cellularity, normal granulopoiesis and erythropoiesis, and absent megakaryocytes. *(Photomicrograph prepared by Dr. Mohamed Abdelhaleem, Toronto.)*

Differential Diagnosis

If CAMT presents at birth or shortly after, it must be distinguished from other causes of severe neonatal thrombocytopenia, which most commonly are caused by severe systemic congenital infections collectively designated as the **TORCH** (***To****xoplasma gondii,* **r**ubella, **c**ytomegalovirus, and **h**erpes simplex virus) **syndrome** or **other neonatal infections** caused by bacteria or viruses. Usually, these infectious etiologies are characterized by increased peripheral destruction of platelets or a combination of peripheral destruction and BM suppression.

Passive transplacental passage of IgG antiplatelet antibodies into fetal circulation can cause rapid destruction of fetal platelets. This occurs in two circumstances: a (1) **maternal autoimmune disease** such as idiopathic thrombocytopenic purpura or systemic lupus erythematosus and (2) in **neonatal alloimmune thrombocytopenia** by alloimmunization of the pregnant mother to fetal antigens inherited from father but absent in the mother. In the former situation, the mother has thrombocytopenia or a history of such; in the latter situation, the mother has a normal platelet count and serum antibodies to human platelet alloantigens.

Thrombocytopenia with absent radii syndrome is distinguished from CAMT because in TAR, the radii are absent. Peripheral blood chromosomes analysis is not associated with increased breakage with DEB or MMC clastogenic stress testing, which allows CAMT to be distinguished from **FA.** Increased platelet destruction also occurs in newborns with giant benign hemangiomas of skin, liver, or spleen, the so-called **Kasabach-Merritt syndrome.**

In an infant or young child with a CAMT clinical diagnosis but without mutant *MPL*, **other inherited forms of thrombocytopenia** should be addressed (see Table 27-5). These can generally be classified according to inheritance pattern (autosomal dominant, autosomal recessive, or X-linked recessive), size of the platelets (small, normal, or large or giant), and presence or absence of associated clinical features. Identification of the specific mutant gene for each disorder confirms the diagnosis.

If CAMT presents beyond the neonatal age period, it must be distinguished from causes of peripheral platelet destruction such as in chronic immune thrombocytopenia purpura, acquired amegakaryocytic thrombocytopenia or aplastic anemia, other inherited BM failure syndromes, MDS, and acute leukemias. The medical history of the patient and family, physical examination, and initial laboratory test results may help to exclude other disorders. However, a BM aspirate and biopsy will point to the diagnosis, and a *MPL* mutational analysis will confirm the diagnosis.

Therapy and Prognosis

Supportive treatment has been largely unsatisfactory to date, and the mortality rate from thrombocytopenic bleeding, complications of aplastic anemia, or malignant myeloid transformation has been very close to 100%. For that reason, HLA typing of family members should be performed as soon as the diagnosis is confirmed to determine if a matched related donor for HSCT exists. If not, a search for

a matched unrelated donor or for a cord blood graft should ensue as soon as the severity of the clinical picture is appreciated. The need for transfusional support is a cogent indication.

Platelet transfusions should be used discretely. Platelet numbers should not be a sole indication; clinical bleeding is a more appropriate trigger for the use of platelets. Single-donor filtered platelets are preferred to multiple unfiltered random donor platelets to minimize sensitization, and if HSCT is a realistic possibility, all blood products should be free of cytomegalovirus and irradiated.

Corticosteroids have been used for thrombocytopenia with no apparent efficacy. Androgens with or without low-dose corticosteroid therapy may induce a partial response, but the effect is short-lived and does not after the long-term outcome.

Based on the in vitro augmentation of megakaryocyte progenitor colony growth in response to IL-3, a small phase I/II clinical trial was initiated for CAMT. IL-3 resulted in improved platelet counts in two of five patients and decreased bleeding and transfusion requirements in the other three. Prolonged IL-3 administration in two additional patients also resulted in platelet increments. This pilot study illustrates that IL-3 may have been an important adjunct to the medical management of CAMT, but it was not adopted broadly and is no longer commercially available. GM-CSF has a positive in vitro effect but not in vivo. Thrombopoietin has not been tried for the treatment of severe type I CAMT and would likely fail because endogenous thrombopoietin levels are markedly increased and the mutated thrombopoietin receptor is nonfunctional. Nevertheless, thrombopoietin agonists that bind to the transmembrane domain might prove efficacious, similar to the in vitro effect of LGD-4665 on cells carrying the F104S *MPL* mutation. LGD-4665 binds to the transmembrane domain of the MPL receptor. Initial application of such a strategy should be assessed as part of clinical trials because of a potential risk of developing hematologic malignancies.

Congenital amegakaryocytic thrombocytopenia can be cured by HSCT. Most of the recent published cases have had successful outcomes. Matched sibling donor sources are ideal even if the donor is a carrier with one mutant allele. Reduced-intensity conditioning regimens for CAMT have been successfully used even in a case with monosomy 7 and in the unrelated donor setting. HSCT using T cell–depleted BM with relatively high $CD34^+$ cell numbers and enhanced T cell–specific immunosuppression in the transplant cytoreductive regimens that have also been successful.

Future Directions

Novel therapy with thrombopoietin receptor agonists may be suitable for type I and type II CAMT patients who retain some MPL function. The cellular consequences of specific gene mutations need to be further studied because this might help to develop novel strategies in patients who do not respond to such therapies. CAMT is also a candidate disease for gene therapy because restoration of wild-type *MPL* would provide in vivo selection of corrected HSCs.

Other Inherited Syndromes With Associated Pancytopenia

Bone marrow failure and cancer predisposition can occur as part of several specific other inherited syndromes and in familial settings that do not exactly correspond with the entities already described.

Down Syndrome

Down syndrome, or constitutional trisomy 21 (+21), has a unique association with aberrant hematologic abnormalities. Three related events can occur. In the neonatal period, a myeloproliferative blood picture with large numbers of circulating blast cells has been observed in approximately 10% of these infants. The blasts show somatic *GATA1* mutations and apparently are clonal but, remarkably, disappear spontaneously over several weeks in most cases. The term *transient myeloproliferative disorder* is often used to describe this unusual clinical picture.

Second, in 20% to 30% of these transient cases, *true* acute megakaryoblastic leukemia (AMKL), also with *GATA1* mutations, appears later and requires treatment. Acute lymphoblastic and myeloblastic leukemias are also seen in Down syndrome, but AMKL is the most common form of myeloblastic leukemia and is estimated to be 500 times greater in children with trisomy 21 than in other children.

Third, the onset of AMKL is frequently preceded by an interval of MDS characterized by thrombocytopenia; abnormal megakaryocytopoiesis; megakaryoblasts in the BM; and an abnormal karyotype, commonly trisomy 8 or monosomy 7. In addition to the propensity for leukemia, a few patients have been reported with aplastic anemia. Of five trisomy 21 with aplastic anemia cases in the literature, three died of BM failure and two responded to androgen therapy.

Dubowitz Syndrome

This is an autosomal recessive disorder characterized by a peculiar facies, infantile eczema, small stature, and mild microcephaly. The face is small with a shallow supraorbital ridge, a nasal bridge at the same level as the forehead, short palpebral fissures, variable ptosis, and micrognathia. This is a rare disorder, and incidence rates for complications are difficult to establish; however, there appears to be a predilection to develop cancer as well as hematopoietic disorders in children with Dubowitz syndrome. Patients have developed acute leukemia, neuroblastoma, and lymphoma. Approximately 10% of patients also develop hematologic abnormalities varying from hypoplastic anemia, moderate pancytopenia, and full-blown aplastic anemia. The mutant gene has not been identified.

Seckel Syndrome

Sometimes called *bird-headed dwarfism,* patients with this autosomal recessive developmental disorder have marked intrauterine and postnatal growth failure, mental deficiency, severe microcephaly, a hypoplastic face with a receding forehead and chin, a prominent curved nose, and low-set or malformed ears. Some patients may show increased chromosomal breakage in lymphocyte cultures with DEB or MMC and mimic FA. About 25% of patients develop aplastic anemia or malignancies. There are possibly five genes linked to Seckel syndrome, all in different cytogenetic locations. Four have been identified: mutant *ATR* has been confirmed for the Seckel 1 subtype; *RBBP8* is responsible for Seckel 2; *CENPJ* for Seckel 4; and *CEP152* for Seckel 5. The abnormal gene for Seckel 3 has been mapped to 14q21-q22. Genotyping will distinguish FA from Seckel syndrome.

Reticular Dysgenesia (Dysgenesis)

This is an immunologic deficiency syndrome coupled with congenital agranulocytosis. The mode of inheritance is autosomal recessive caused by biallelic mutations in mitochondrial *AK2*. The disorder is a variant of severe combined immune deficiency in which cellular and humoral immunity are absent; patients also have severe lymphopenia and neutropenia. Because of profoundly compromised immunity, the syndrome presents early with severe infection at birth or shortly thereafter. A striking feature is absent lymph nodes and tonsils and an absent thymic shadow on radiographs. In addition to lymphopenia and neutropenia, anemia and thrombocytopenia may be present. BM specimens are hypocellular with markedly reduced myeloid and lymphoid elements. Clonogenic assays of hematopoietic progenitors consistently show reduced to absent colony growth, indicating that the disorder has its origins at the HSC level. The only curative therapy is HSCT.

Schimke Immunoosseous Dysplasia

Schimke immunoosseous dysplasia is an autosomal recessive disorder caused by mutations in the chromatin remodelling gene *SMARCAL1* in 50% to 60% of patients. Patients manifest spondyloepiphyseal dysplasia with exaggerated lumbar lordosis and a protruding abdomen. They have pigmentary skin changes and abnormally discolored and configured teeth. Renal dysfunction can be problematic with proteinuria and nephrotic syndrome. Approximately 50% of patients have hypothyroidism and 50% have cerebral ischemia; 50% have anemia, 50% have neutropenia, 30% have thrombocytopenia, and 10% have aplastic anemia. Lymphopenia and altered cellular immunity are present in 80% of patients. One patient has undergone a successful stem cell transplantation.

Noonan Syndrome

Noonan syndrome (NS) is a developmental disorder characterized by the *Noonan facies* (hypertelorism, ptosis, short neck, low-set ears), short stature, congenital heart disease, and multiple skeletal and hematologic abnormalities. The literature describes several NS patients who developed amegakaryocytic thrombocytopenia and another who developed pancytopenia and a hypocellular BM. NS is an autosomal dominant disorder with genetic heterogeneity. So far, heterozygous germline mutations in nine genes (*PTPN11, SOS1, KRAS, NRAS, RAF1, BRAF, SHOC2, MEK1,* and *CBL*) underlie the disorder in 75% of cases. These genes encode for proteins in the RAS-mitogen–activated protein kinases signal transduction pathway. A variant of neurofibromatosis type 1(NF1) caused by germline mutations in the *NF1* gene shares a phenotypic overlap disorder with NS, the so-called *neurofibromatosis–Noonan syndrome*. Remarkably, children with NF1 and with NS both have an increased risk of juvenile myelomonocytic leukemia (JMML), a rare, aggressive hematologic cancer with onset in the first few years of life. Of note, three of the mutated genes that cause NS (*PTPN11, KRAS,* and *NRAS*) are also found as somatic mutations in BM cells from children with JMML.

Cartilage-Hair Hypoplasia

Cartilage-hair hypoplasia (CHH) is an autosomal recessive syndrome characterized by metaphyseal dysostosis; short-limbed dwarfism; and fine, sparse hair. Additional skeletal findings include scoliosis, lordosis, chest deformity, and varus lower limbs. Aganglionic megacolon and other gastrointestinal abnormalities have been reported. Most cases in the literature are Finnish or Amish. Mutations in the noncoding RNA gene *RMRP* are seen in more than 80% of cases. Macrocytic anemia of varying severity is seen in the majority of patients. Most patients have mild and self-limited anemia, but some are severe and persistent resembling Diamond-Blackfan anemia and require RBC transfusions. Severe immunodeficiency can occur, often with the severe anemia. HSCT has been used successfully to reconstitute the immune system. Neutropenia has been reported in 25% of CHH cases and lymphopenia in 65%. Lymphomas and basal cell carcinoma also occur at an increased frequency.

Pearson Syndrome

Pearson syndrome is an inherited failure of BM and, in 30% of cases, impaired exocrine pancreatic function caused by acinar cell atrophy and fibrosis. Patients with Pearson syndrome have a maternally inherited diagnostic deletion of mtDNA that encodes enzymes that are critical to oxidative phosphorylation. The genetic deletion results in a syndrome of refractory anemia with ringed sideroblasts and prominent vacuolization of BM erythroid and myeloid precursors. Physical malformations are rarely observed. Severe anemia requiring transfusions is present within the first year of life, sometimes at birth. Pancytopenia may occur alone or in association with hepatic failure and a renal tubulopathy leading to lactic acidosis. The projected median survival time is 4 years. Anemia is managed with RBC and platelet transfusional support. Erythropoietin has been used for the anemia of renal failure. G-CSF is indicated for severe neutropenia. The need for pancreatic enzyme replacement is unclear.

Other Unclassified Inherited Forms of Bone Marrow Failure

Bone marrow failure can cluster in families, but many of these cases cannot be readily classified into discrete diagnostic entities such as FA, SDS, or DC. The phenotype of these familial conditions can be complex with varying combinations of cytopenias, macrocytosis, elevated levels of HbF, hypocellular BM, immunologic deficiency, physical malformations, and predisposition to leukemia. The BM failure appears to be the result of a complex interplay of mutant genes, modifying genes, epigenetic processes, acquired factors, and chance effects that may be specific to each affected family. Published examples of unclassified familial forms of BM failure have been reviewed and divided into inheritance patterns, and then subdivided into cases with and without physical anomalies.

Using the Canada-wide database of the CIMFR, a unique study was launched on IBMFs cases that were deemed unclassifiable at study entry. Of 162 enrolled patients, 39 were registered as having an unclassified disorder. Although the hematologic phenotypes were similar to the classified syndromes in the registry (single- or multilineage cytopenia, severe aplastic anemia, MDS, AML, and cancer), the patients presented at an older age (median, 9 months vs. median 1 month for classified), and the variation in clinical presentations was substantial. Grouping patients according to physical abnormalities and hematologic phenotype was not always sufficient to characterize or diagnose a condition because affected members from several families fit into different phenotypic groupings. It was difficult to formulate a sensible and cost-effective diagnostic workup based on the family histories and hematologic and physical findings. Compared with workups of classifiable syndromes, clastogenic chromosomal fragility testing and extensive genotyping efforts of the unclassified cases required use of several-fold higher specific diagnostic tests at a cost that was 4.5 times higher per evaluated patient. Despite these efforts and the huge, recent explosion of gene discovery, only 20% of unclassified patients were diagnosed with a specific syndrome, underscoring ongoing diagnostic limitations for these disorders.

Treatment of Unclassified Familial Forms of Bone Marrow Failure

Because these disorders are rare, broad conclusions about management are difficult to formulate. For full-blown aplastic anemia with a hypocellular, fatty BM or for MDS/AML, curative therapy with HSCT remains the first choice if a suitable donor is identified. In the familial cases, potential related stem cell donors must be thoroughly assessed clinically, hematologically, and by diagnostic laboratory testing to ensure that latent or masked BM dysfunction is not present. If a matched sibling donor is not available, an unrelated donor search should be initiated, and in the interim, principles of medical management used for FA and for acquired aplastic anemia should be used.

UNILINEAGE CYTOPENIAS

Diamond-Blackfan Anemia

Background

Diamond-Blackfan anemia, previously called *congenital hypoplastic anemia,* is an inherited form of pure RBC aplasia. The syndrome is

heterogeneous with respect to genetic causes, clinical and laboratory findings, in vitro data, and therapeutic outcome. DBA is the first disease to be identified as a *ribosomopathy*. It is also the best example of the ribosomopathies because all currently known DBA genes are components of the small or large ribosome subunits. However, only about 55% of the patients can now be genotyped; thus, it is still possible that different pathways are affected by undiscovered DBA genes. All genetically proven cases show autosomal dominant inheritance with variable penetrance. Recessive inheritance was inferred in more than 30 families published in the literature that had affected siblings with normal parents, affected cousins, or consanguinity. However, these cases have not been confirmed as autosomal recessive. Some of these may be autosomal dominant with partial penetrance or arise from gonadal mosaicism.

Epidemiology

Based on data from a European registry of DBA patients, the estimated incidence of the disorder as assessed for France over a 13-year period was 7.3 cases per million live births. Data from the Canadian Registry show an incidence of 10.4 cases per million live births as assessed over a 9-year period. Although the majority of published patients are white, DBA has been recognized in several ethnic groups, including African blacks, Arabs, East Indians, and Japanese.

In terms of gender distribution, both sexes are equally affected. About 80% of DBA cases are sporadic.

Etiology, Genetics, and Pathophysiology

The discovery of nine DBA genes (see Table 27-1) demonstrates heterozygosity for mutations in the respective genes consistent with autosomal dominant inheritance in all currently known genetic groups. All known DBA proteins are structural components of either the small or large ribosomal subunits.

In most DBA cases peripheral blood karyotype is normal, although alterations of chromosomes 1 and 16 have been reported. Discovery of a balanced reciprocal translocation t(x;19) in a sporadic female case of DBA and the identification of microdeletions on chromosome 19 in some other DBA patients led to the identification of the first DBA gene mutation. Subsequent studies revealed mutations in one allele for the gene in 25% of patients, and it is currently the most common known mutant DBA gene.

RPS19 protein is a component of the ribosomal 40S subunit. Multiple other genes encoding either the 40S small ribosome subunit or 60S ribosome subunit have been subsequently identified in DBA. The second most commonly mutated gene in DBA is *RPL5.* It is mutated in 12% to 21% of the patients. Other mutated genes are *RPL11* (7%-9% of the patients), *RPS26* (10%), *RPS10* (4%), *RPS24* (2%), *RPL35a* (2%), *RPS17* (<1%), and *RPS7* (<1%). Alterations in *RPL30, RPS15,* and *RPS27a* have also been identified, but the etiologic significance of these alterations is still unclear. Despite the identification of many mutated genes in DBA, only about 55% of the patients with DBA can now be genotyped.

Recent studies have shed light on the function of the RPS19 protein in ribosome biogenesis. RPS19 associates with the ribosomal subunit 40S. It is critical for normal maturation of rRNA because its deficiency causes defective cleavage of the pre-rRNA at the ITS1 sequence and abnormal maturation of the 40S subunit. This leads to accumulation of faulty pre-40S ribosome subunits.

Other ribosomal proteins that are mutated in DBA are also critical for ribosome biogenesis, For example, it has been shown that the yeast RPL11 is positioned at the intersubunit cleft of the large ribosome subunit central protuberance, thereby forming an intersubunit bridge with the small subunit protein S18. Mutations in this region such as F96 and A66 lead to halfmer formation. Mutations in RPS24 also impair pre-rRNA processing of the 18S rRNA and decrease the production of the 40S ribosomal subunit. On the other hand, depletion of RPL35A reduces the amount of the 60S subunit and of the mature 80S ribosomes.

The mechanism by which RP gene mutations impairs RBC development remains unknown. In 25% of cases with mutant *RPS19,* the prevailing opinion is that the disorder results from protein haploinsufficiency. In support of this, two classes of *RPS19* mutations have been described: quantitative defects resulting in undetectable protein and hotspot mutations leading to loss of function. Additional links between *RPS19* and erythropoiesis have now been clearly established. Defective erythropoiesis ensues when *RPS19* is knocked down in cellular models. In addition, wild-type gene transfer corrects the defective erythropoiesis in *RPS19*-deficient DBA CD34+ cells resulting in a threefold increase in erythroid colony growth. In yeast, the introduction of *RPS19* mutations found in DBA results in a defect in the processing of pre-rRNA similar to that observed in DBA cells with decreased expression of *RPS19*.

A large body of evidence indicates that the erythroid progenitor compartment is intrinsically defective in DBA. Standard clonogenic assays for CFU-E and BFU-E progenitors consistently have shown reduced or absent colonies in most DBA patients and intermediate, normal, or occasionally increased numbers in the rest. The DBA erythroid progenitors are relatively insensitive to erythropoietin in vitro and to burst-promoting activity, but the hyporesponsiveness to erythropoietin can be corrected in some cases by the addition of glucocorticoids in vitro or by clinically administering prednisone.

The data underscore the fact that the intrinsic defect of DBA erythroid progenitors is an inability to respond normally to inducers of erythroid proliferation, differentiation, or both. Indeed, DBA $CD34^+$ HSCs/early progenitors differentiate normally along megakaryocytic and granulocytic pathways in short-term cultures but aberrantly along the erythroid lineage. Accelerated programmed cell death (apoptosis) plays a central role in this pathogenesis as it does in many, if not all, inherited BM failure disorders. A role for induction of apoptosis by the Fas–Fas ligand system in DBA was suggested because of elevated serum soluble Fas ligand in patients compared with control participants. Based on the various patterns of erythroid colony growth seen with DBA patients, a model for the aberrant erythropoiesis was developed that proposes maturational arrest at varying sites along the differentiation pathway.

The combination of recombinant IL-3 and Steel factor (SCF) increases the in vitro clonogenicity of DBA BM progenitors. The size and number of DBA BFU-E colonies are dramatically increased. The data on the effect of IL3, SCF, or GM-CSF as single agents is less conclusive. The human ligand for flt-3 apparently has no effect on DBA BM colony growth. However, addition of IL-9 to SCF, IL-3, and erythropoietin does potentiate DBA BFU-E growth.

There are significant age-related changes in erythroid and granulopoietic progenitors in DBA patients. Despite profound anemia, seven of 10 patients studied within 1 year of diagnosis had normal numbers of CFU-E and BFU-E that showed a normal response to cytokines. In contrast, 12 of 14 patients followed more than 3 years had decreased erythroid progenitors and, in seven cases, decreased CFU-GM. The data are consistent with the idea that the DBA defect involves other hematopoietic lineages and worsens with time.

Strong support for this conclusion comes from a detailed study that examined the interaction between DBA $CD34^+$ cells and the hematopoietic microenvironment using long-term BM cultures. Stromal adherent layers from DBA patients did not show evidence of any morphologic, phenotypic, or functional abnormality, and the stroma sustained the proliferation of normal $CD34^+$ cells. A major finding was an impaired capacity of DBA $CD34^+$ cells in the presence of normal stromal cells to proliferate and differentiate along not only the erythroid pathway but also along the granulocytic–macrophage pathway. These results indicate an intrinsic defect of a hematopoietic progenitor with at least bilineage potential that places it earlier than previously suspected and that was only unmasked by testing in long-term cultures. This observation, however, is in keeping with the clinical observation that in addition to anemia, patients may have neutropenia and thrombocytopenia. These findings were extended

with evidence in long-term culture initiating assays for a trilineage defect in DBA refractory to treatment. The data broaden the definition of DBA and explain generalized BM dysfunction and hypoplasia in some cases of DBA that have puzzled investigators for years.

The molecular mechanism that links ribosome protein haploinsufficiency to the erythroid defect is unclear. One hypothesis is that it is related to translation insufficiency. It is well known that during early stages of erythropoiesis, translation is increased. It is possible that the need for protein synthesis is not met during this critical developmental stage. A second hypothesis is that *RP* gene mutations lead to accumulation of abnormal rRNA precursors as well as dysregulation of multiple ribosomal protein genes and protein expression as shown with *RPS19*. This leads to defective ribosome biogenesis, unassembled ribosome proteins, and possibly cellular stress.

A third hypothesis and the one considered most plausible is that defective ribosome biogenesis leads to activation of p53, thereby causing apoptosis and cell cycle arrest. A role of p53 is supported by a recent mouse model with mutations in *RPS19* that is characterized by RBC underproduction and small mouse size and by zebrafish models of *RPS19* inhibition that manifest impaired erythropoiesis and malformations. Activation of p53 may involve the interactions of MDM2 with specific ribosomal proteins such as RPL5, RPL11, and RPL23. These interactions may lead to dissociation of p53 from MDM2, impairment of p53 targeting to the proteosome, and prevention of proteosome degradation. However, these models do not explain how haploinsufficiency of RPL5 and RPL11 leads to p53 activation.

Extraribosomal functions have been ascribed to various RP genes that might mediate BM failure. For example, RPS19 has been shown to interact with a nucleolar protein S19-binding protein (S19BP), fibroblast growth factor 2, and the PIM-1 oncoprotein. PIM-1 is an ubiquitous serine-threonine kinase, the expression of which can be induced in erythropoietic cells by several growth factors, including erythropoietin. Thus, there may be a possible link between erythropoietic growth factor signaling and RPS19.

The erythroid lineage is predominantly impaired in DBA for unknown reasons. Studies have shown that the heme exporter FLVCR1 is critical for CFU-E development. Knocking out FLVCR1 in mice causes impaired CFU-E development. A partial block in human FLVCR1 in $CD34^+$ HSCs recapitulates the hematologic features of DBA, including $CD36^+/CD135a^+$ erythroid progenitor cell development but not myeloid cell development. Importantly, 55% to 95% of the *FLVCR1* transcript is alternatively spliced in DBA cells compared with 4% to 24% in normal immature erythroid cells. The spliced variants in DBA encode *FLVCR1* proteins that are defective in their cellular and surface expression and in their function. It is possible that expression of *FLVCR1* splicing variants leads to impaired export of intracellular iron and apoptosis because of accumulation of iron.

Patients with mutations in *RPL5* and *RPL11* are more likely to have multiple physical malformations. For example, thumb anomalies are seen in 56% and 39% of the patients with *RPL5* and *RPL11* mutations, respectively, compared with 7% in patients who have *RPS19* gene mutations. Interestingly, cleft lip or palate was reported in 42% of the patients with *RPL5* mutations compared with 6% and 0% of the patients with *RPL11* and *RPS19* gene mutations, respectively.

Clinical Features

Diamond-Blackfan anemia registries with longitudinal data and a summary of published cases provide comprehensive information about clinical aspects of the disorder. Aside from findings associated with anemia, about half of infants at presentation look healthy and are normal physically. Unless the baby develops cardiac failure as a result of anemia, hepatosplenomegaly and edema are absent.

Pregnancy, birth history, or both are often abnormal. In a survey from the French and German DBA registries of 64 pregnancies in 26 women with DBA, complications were seen in 42 pregnancies (66%) and included abortion, preeclampsia, in utero fetal death, in utero growth retardation, retroplacental hematoma, and preterm delivery. Thirteen of 34 children born alive had DBA. Fetal DBA with hydrops fetalis has been reported. More than 90% of cases present in the first 12 months of life.

About 30% to 47% of patients present with one or more congenital anomalies. Most of these phenotypic abnormalities belong to the following categories: (1) craniofacial dysmorphism, including hypertelorism, microcephaly, microphthalmos, congenital cataract or glaucoma, strabismus, microretrognathism, and a high-arched palate or cleft palate; (2) prenatal or postnatal growth failure independent of steroid therapy; (3) neck anomalies, which may consist of a pterygium coli or the fusion of cervical vertebrae with flaring of the trapezius muscle (Klippel-Feil syndrome), giving a Turner syndrome appearance or there may also be the Sprengel deformity (congenital elevation of the scapula) as an isolated anomaly or a combination of the two anomalies; and (4) thumb malformations, such as bifid thumb (Fig. 27-7), duplication, subluxation, hypoplasia, or absence of the thumb. There is a characteristic association of triphalangeal thumbs with DBA (Fig. 27-8) commonly referred to as "Aase syndrome II" or "Aase-Smith syndrome." In addition, some patients have a flat, hypoplastic thenar eminence, weak or absent radial pulses, or both, which probably represent variations of the thumb malformations.

Some patients have a characteristic facial appearance. The facies of individuals with DBA is said to consist of tow-colored hair, a snub nose, wide-set eyes, a thick upper lip, and an intelligent expression. Another facies observed in two unrelated girls of markedly different ancestries consists of small heads, almond-shaped eyes with a slight antimongoloid slant, a "fish-like" smile, and a pointed chin. These patients resemble each other more than they resemble their own

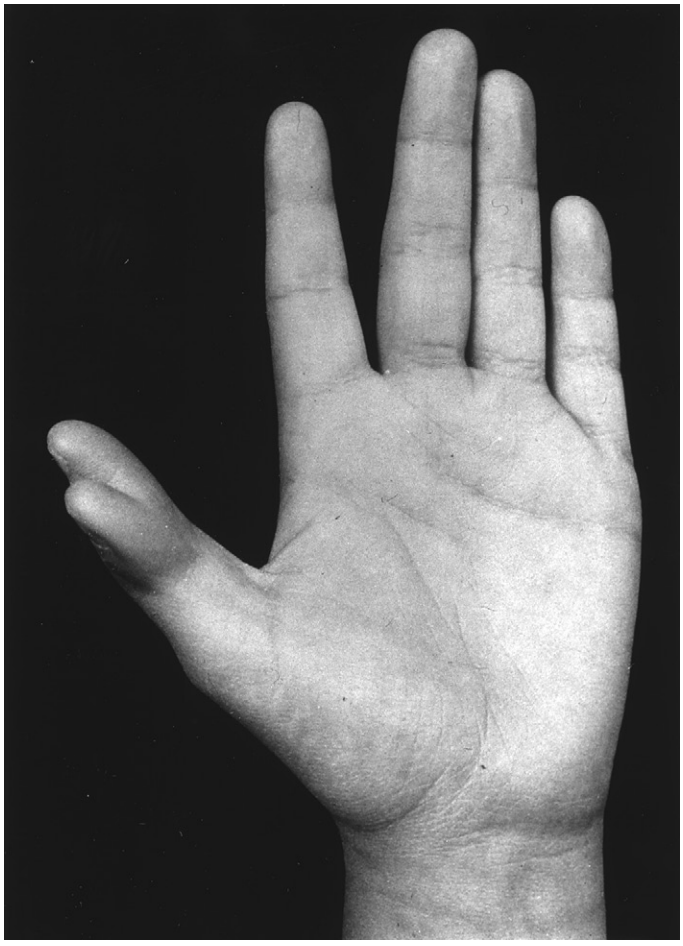

Figure 27-7 BIFID THUMB IN DIAMOND-BLACKFAN ANEMIA.

family members (Figs. 27-9, *A* and 27-9, *B*). Some patients with DBA have a phenotype indistinguishable from Treacher-Collins syndrome, a disorder of ribosome biogenesis caused by *TCOF1* mutations.

Various other anomalies are occasionally reported in association with DBA. There may be urogenital malformations, such as dysplastic or horseshoe kidneys, duplication of ureters, or renal tubular acidosis. There may also be congenital heart disease, mainly ventricular and atrial septal defects, or hypogonadism, ear malformations, mental retardation, congenital hip dislocation, or tracheoesophageal fistula.

Figure 27-8 RADIOGRAPH OF A TRIPHALANGEAL THUMB IN DIAMOND-BLACKFAN ANEMIA.

Laboratory Findings

Peripheral Blood and Bone Marrow. The main hematologic findings in DBA are summarized in Table 27-6. The anemia is usually profound at the time of diagnosis. Hemoglobin levels average 6.5 g/dL in patients diagnosed in the first 2 months of life (range, 1.7-9.1 g/dL) and 4.0 g/dL (range, 1.8-7.4 g/dL) in those diagnosed later. In the vast majority of patients, the MCV is above the expected values for age. The peripheral blood smear may show, in addition to macrocytes, a mild degree of nonspecific anisocytosis and poikilocytosis. The aregenerative component of the anemia is reflected by the absence of both polychromasia and nucleated RBCs on the blood film. Decreased RBC production is confirmed by the absence of a reticulocyte response and by characteristic findings on BM examination.

In more than 90% of patients, the BM aspirate is normocellular, but erythroblasts are markedly decreased or absent. Proerythroblasts, if present, account for less than 3% of all nucleated elements, with a myeloid-to-erythroid ratio of 10 to 1 (Fig. 27-10). In 5% to 10% of cases, proerythroblasts may be present in normal numbers, with or without a maturation arrest. The other cell lines are normal. White blood cell counts and platelet counts are usually normal at diagnosis, but platelets may be decreased or increased and with normal function. Mild to moderate neutropenia, thrombocytopenia, or both may occur later in the course of the disease. Progression of the single-lineage erythroid deficiency of DBA into pancytopenia and severe aplastic anemia is rare but occurs. Of 36 deaths reported to the American Diamond-Blackfan Anemia Registry (DBAR), one died from severe aplastic anemia.

Erythrocyte Findings. Erythrocytes in DBA express a number of fetal characteristics. The level of HbF is increased persistently even during remission. It remains at a level of 5% to 10% after the age of

A B

Figure 27-9 SIMILAR DIAMOND-BLACKFAN FACIES IN TWO UNRELATED GIRLS OF DIFFERENT ANCESTRIES CONSSTING OF A SMALL HEAD, ALMOND-SHAPED EYES WITH A SLIGHT ANTIMONGOLOID SLANT, A "FISH-LIKE" SMILE, AND A POINTED CHIN.

Table 27-6 Hematologic Features in Diamond-Blackfan Anemia at Diagnosis Based on Data on 21 Toronto Cases and on 41 Cases From the Canadian Inherited Marrow Failure Registry

Hematologic Parameters	Laboratory Findings
Mean hemoglobin value (range)	
Newborns younger than 2 months of age	6.5 g/dL (1.7-9.1 g/dL)
Children 2 months of age or older	4.0 g/dL (1.8-7.4 g/dL)
High MCV for age after the age of 1 year	87%
Low reticulocyte for the degree of anemia	100% (usually markedly decreased to <1%)
Increased HbF for age after 1 year of age	100%
RBC adenosine deaminase activity	77%
RBC i antigen	Expression increased beyond first year of life
RBC enzymes	Fetal pattern
Neutropenia	31%
Thrombocytopenia	11%
BM cellularity	Normal or increased in 90%; mildly reduced in 10%
BM erythropoiesis	Markedly reduced/absent erythroid precursors in >90% of cases
BM myeloid and megakaryocytic lineages	Normal in 100% of the cases

BM, Bone marrow; *HbF,* fetal hemoglobin; *MCV,* mean corpuscular volume; *RBC,* red blood cell.

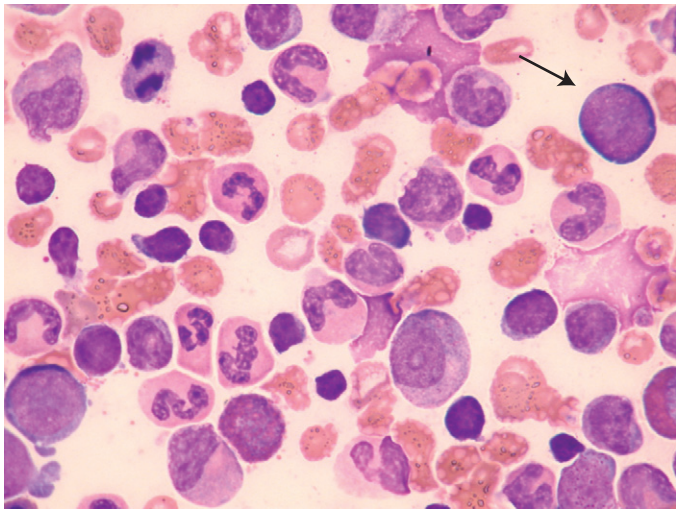

Figure 27-10 HIGH-POWER VIEW OF A BONE MARROW ASPIRATE FROM A NEWLY DIAGNOSED INFANT WITH DIAMOND-BLACKFAN ANEMIA. The findings are active granulopoiesis; normal lymphoid activity for age; and an isolated pronormoblast *(arrow)* with total absence of early-, intermediate-, and late-stage nucleated red blood cells. *(Photomicrograph prepared by Dr. Mohamed Abdelhaleem, Toronto.)*

6 months and has a heterogeneous distribution in RBCs. The HbF has a specifically fetal amino-acid profile with a high glycine-to-alanine ratio (G-γ:A-γ). Similarly, the i antigen, which normally disappears from the erythrocyte surface by 1 year of age, is expressed at near fetal levels in older patients with DBA.

The precise cause of this fetal-like erythropoiesis is unclear. It is clearly distinct from the fetal erythropoiesis implicated in various types of leukemia, notably in juvenile myelomonocytic leukemia in which the fetal RBCs presumably arise from the leukemic clone. The situation in DBA may be analogous to that in other forms of BM failure and in the hematologic recovery phase after BMT. In all of these conditions, the fetal (or "stress") erythropoiesis may represent an accelerated recapitulation of RBC ontogeny in the face of an increased demand for new RBCs in peripheral blood.

Red blood cell enzymes often display an abnormal pattern of activity that reflects a fetal expression pattern of RBC glycolytic and hexose monophosphate shunt enzyme activities. Enzymes, such as enolase, glyceraldehyde-3-phosphate dehydrogenase, phosphofructokinase, and glutathione peroxidase, have increased activity in patients with DBA compared with those in normal children and adults and in patients with transient erythroblastopenia of childhood (TEC). For some enzymes, this increased activity is comparable to cord blood RBCs. In apparent contradiction, carbonic anhydrase isoenzyme B, which is not normally present in fetal RBCs, was detected in hemolysates from three patients with DBA. Also, the RBCs of two of the three patients had adult hexokinase isoenzyme distribution by isoelectric focusing.

Abnormalities in purine and pyrimidine metabolism are reflected by increased activity of RBC adenosine deaminase (ADA) in 60% to 90% of the patients with DBA. Also, increased orotidine decarboxylase (ODC) activity is seen in some patients. ADA activity is raised in DBA erythrocytes but not in cord blood RBCs from normal newborns or from patients with any of several hematologic conditions associated with "stress" erythropoiesis. Thus, this enzymatic abnormality cannot be simply attributable to a "reversion" to fetal erythropoiesis. Raised ADA activity may also be detected in some hemolytic anemias and acute leukemias, which limits the utility of this assay as a specific diagnostic marker for DBA. However, increased ADA activity does appear to be useful in differentiating DBA from acquired pure cell anemias such as TEC and for epidemiologic testing of DBA pedigrees to identify family members with a mild phenotype.

Miscellaneous Findings. Serum levels of various factors involved in RBC production, such as erythropoietin, iron, vitamin B_{12}, and folate, are appropriately elevated in DBA. These findings are compatible with any form of chronic hypoplastic anemia. Riboflavin levels are normal in the serum but not in the erythrocytes. This observation initially aroused interest because experimental riboflavin deficiency may be corrected by corticosteroids similar to DBA. However, administration of large doses of riboflavin to several DBA patients did not result in a hematopoietic response. RBC serology is usually unremarkable at the time of diagnosis, but alloantibodies are frequently detected in chronically transfused patients.

Imaging Studies. Imaging studies are frequently informative and assist in establishing a diagnosis. Skeletal radiography may define abnormalities suspected from physical examination, such as hypoplastic, absent, or extra phalanges. Ultrasound of the abdomen may reveal malformations such as of the urogenital system. Echocardiography may reveal undiagnosed cardiac defects.

Differential Diagnosis

The diagnosis of DBA is made if the patients have at least two of the following criteria (1) pure RBC aplasia as documented by normochromic-macrocytic anemia, relative reticulocytopenia, and normocellular BM with a selective deficiency of RBC precursors; (2) classical constellation of physical malformations; (3) a first-degree relative with DBA; or (4) a mutation in a DBA gene.

Table 27-7 Distinguishing Features Between Diamond–Blackfan Anemia (DBA) and Transient Erythroblastopenia of Childhood (TEC)

	DBA	TEC
Etiology	Genetic	Acquired
Immune mediated	None	Common
Family history	≈10%	Occasional siblings with concurrent TEC
Antecedent history	None	Viral infection
Age at diagnosis	90% by 1 year	6 months-4 years
Physical anomalies	≈50%	None
Neurologic findings	None	Occasional
Transfusion dependence	Yes, if steroid refractory	None
Course	Chronic	Full recovery
Risk of cancer	Increased	Not increased
Risk of MDS or leukemia	Increased	Not increased
Laboratory findings at diagnosis:		
RBC size	Macrocytic	Normocytic
HbF	Increased	Normal*
i Antigen	Increased	Normal*
RBC enzyme activities	Fetal levels	Adult levels
RBC adenosine deaminase	Increased in 40%-90%	Normal

HbF, Fetal hemoglobin; *MDS,* myelodysplastic syndrome; *RBC,* red blood cell; *TEC,* transient erythroblastopenia of childhood.
*During spontaneous recovery, values may be increased.

In clinical practice, after excluding a viral etiology, particularly parvovirus B_{19}, **TEC** is usually the main diagnosis that is confused with DBA (Table 27-7). Both entities share the same morphologic findings in the BM. However, TEC is a self-limited disorder with an excellent prognosis and needs no specific therapy except for RBC transfusions in the most profoundly anemic patients. The definition of TEC includes the following features: (1) gradual onset of pallor in previously healthy children usually 1 to 4 years of age (85% of cases); (2) normochromic-normocytic anemia with varying reticulocytopenia unless recovery has already ensued; (3) BM erythroid hypoplasia (60% of cases) or aplasia (10% of cases) or a recovery picture (30% of cases); and (4) spontaneous recovery usually within 4 to 8 weeks without recurrence, with rare exceptions.

There are some additional important features of TEC. It can occur in siblings simultaneously and in seasonal "clusters" from June to October and from November to March. Of concern are the transient neurologic changes that can accompany TEC and that appear to be linked to the disorder. Affected children may have one or more of the following: hemiparesis, papilledema, abnormal extraocular movements, seizures, and unsteadiness of gait. The affected patients in the published reports recovered without sequelae, and the precise relationship of these neurologic changes to the pathogenesis of TEC has not been determined.

It was claimed initially that only the erythroid lineage was affected in TEC and all other hematopoietic lineages were normal. Nevertheless, significant neutropenia also occurs in many patients with TEC, being associated in some with hypocellular BM or with a granulopoietic maturational arrest. The neutropenia may be caused by a common pathogenetic mechanism that produces anemia. An unusual presentation of TEC as a leukoerythroblastic anemia has been recorded, possibly reflecting a recovery stage.

Although one case of TEC was caused by parvovirus B19, no data firmly incriminate other infectious agents in the etiology of TEC, although a history of a preceding viral-like illness can be obtained in more than half of the patients. The most plausible explanation proposed to date is that TEC is caused by transient immunosuppression of erythropoiesis and possibly of granulopoiesis in those with neutropenia. Increased numbers of $CD10^+$ lymphoid cells in BM of TEC patients might be an indication for such a mechanism. Most supportive evidence for this hypothesis comes from in vitro studies. Two reports described an inhibitory effect of TEC serum and fractionated IgG on erythroid colony growth that disappeared as TEC improved. An IgG inhibitor of erythropoiesis was discovered in one case and an IgM inhibitor in a second patient. A summary of other published studies suggests that more than 60% of TEC patients have autologous or allogeneic serum inhibitors of erythroid colony formation. Autologous or allogeneic cell-mediated immune suppression of erythropoiesis has also been identified in about 25% of cases. All of the in vitro studies have generated varying patterns of erythroid colony growth in TEC. Colony numbers can be normal, but reduced numbers of BFU-E and CFU-E progenitors have been recorded in 30% and 50% of cases, respectively.

Therefore, TEC has an autoimmune pathogenesis. TEC cases are not caused by DBA mutations. The transient nature of TEC is similar to other autoimmune hematologic disorders of childhood such as immune thrombocytopenia purpura and some cases of autoimmune hemolytic anemia. The decreased activities of virtually all RBC enzymes in TEC compared with control participants probably relate to the aged population of peripheral blood erythrocytes being tested.

Regarding **viral causes** of non-DBA RBC aplasia, Epstein-Barr virus, hepatitis virus, human T-cell leukemia virus-1, and human immunodeficiency virus-1 have all been implicated and should be excluded if the etiology of the anemia remains unclear. Parvovirus B_{19} stands out as a major causal agent of RBC aplasia in the context of an underlying chronic hemolytic anemia in infants and children with chronic congenital and acquired forms of immunosuppression. Fetuses are uniquely susceptible to parvovirus infection, and in utero transmission is a well-documented cause of nonimmune hydrops fetalis. Parvovirus infection should be ruled out in every case of childhood RBC aplasia by serial measurements of serum IgM and IgG and by BM examination for the characteristic giant pronormoblasts. Parvovirus may also be detected in BM by gene amplification using PCR and confirmed by direct in situ hybridization.

Rarely, the initial hematologic manifestation of several other inherited BM failure syndrome such as **FA** and **congenital hair hypoplasia** is isolated macrocytic anemia. Specific screening testing for these conditions might be necessary. Milder forms of **mitochondrial DNA deletion syndromes** can also present with macrocytic anemia.

Predisposition to Malignancy

Diamond-Blackfan anemia is associated with hematologic cancer and with solid tumors, albeit to a much lesser degree than FA, DC, SDS, and Kstmann/severe congenital neutropenia (K/SCN). The link between DBA and hematologic cancer is more understandable from the data described herein that implicate an early pluripotent BM progenitor in the pathobiology of DBA. From published data, 10 DBA patients developed AML, 2 developed MDS, 1 had acute lymphoblastic leukemia, 3 had Hodgkin lymphoma, and 1 had non-Hodgkin lymphoma. Regarding solid tumors, a predilection to osteosarcoma was reported in 6 of the 11 solid tumors. The other solid tumors included HCC, breast carcinoma, gastric carcinoma, vaginal melanoma, and malignant fibrous histiocytoma. Although the actuarial risk of cancer in DBA is unknown, the risk exists, and hence DBA is considered to be a cancer predisposition syndrome. The published cases implicate several possible operative factors, including genetic predisposition, transfusional iron overload, use of androgens, immunosuppression from corticosteroids, thymic and skeletal irradiation during childhood as "therapy" for DBA in one case, and cyclophosphamide "treatment" in another. It is noteworthy that inhibition of ribosome protein genes in zebrafish is associated with the development of cancer.

Natural History and Prognosis

Historically, the only treatment for DBA was blood transfusions. Without this, patients died of anemia. When corticosteroids were introduced as an effective therapy for DBA, all patients were assigned to one of the two therapeutic interventions, and the "natural history" of the disorder took on a different dimension.

A notable phenomenon is spontaneous remission that occurs in about 20% of cases that allows patients to discontinue whatever treatment they are receiving, either chronic transfusion therapy or corticosteroids. The DBAR has actuarial data showing that 75% of these patients remit before their 10th birthday, and in most cases, the remission is sustained. It appears that an equal number of patients remit from either corticosteroids or transfusions. A relapse of DBA requires reintroduction of treatment.

The overall actuarial survival for DBA patients greater than 40 years of age is 75% ± 4.8%. For those in sustained spontaneous remission, it is 100%; for corticosteroid responders, it is 57% ± 8.9%; and for transfusion-dependent patients, it is 8.9%. Causes of death mostly relate directly to the development of cancer or its treatment, complications from corticosteroid-induced immunosuppression, stem cell transplant–related complications, and transfusional hemosiderosis.

Therapy

In younger children and infants, it is important to determine whether the RBC aplasia is DBA or TEC (see Table 27-7). Until a firm diagnosis is established, the initial treatment in children is almost always transfusions. This allows the flexibility to complete the viral workup and other investigations and to await a spontaneous remission if the anemia is caused by TEC or another self-limited condition. Demonstration of a mutant ribosomal protein gene would clinch the diagnosis, but it occurs in only about 55% of patients.

If transfusions are used, it is recommended to aim for a moderate but not full correction of anemia so that erythropoiesis is not suppressed and recovery from TEC not delayed. Generally, the nadir should not be less than 6 g/dL and should not allow the development of significant symptoms. Most patients with TEC usually recover within a few weeks after receiving only one transfusion. Occasionally, recovery from TEC is slow and may mimic DBA in chronicity. If there is confusion about the proper diagnosis, it is appropriate to withhold corticosteroids in favor of a further transfusion to allow more observation time.

Transfusions for Patients With Diamond-Blackfan Anemia

Before the first transfusion, it is recommended that a full RBC phenotype be performed on the patient. This information is valuable for prevention and management of alloantibody formation caused by sensitization. For patients in whom corticosteroids are either ineffective or excessively toxic, a regular program of RBC transfusions is usually required. During the course of this program, a small number of steroid-resistant patients may show responsiveness to corticosteroids when retreated or even proceed to a spontaneous transient or prolonged remission. If not, leukocyte-depleted packed RBCs are given monthly to keep the hemoglobin concentration at a level compatible with normal activity; usually above 9 g/L. CMV-negative packed cells should be used if stem cell transplantation is contemplated. Several complications may arise from transfusions such as bloodborne infections and sensitization, but the major long-term threat is iron overload, which causes delayed puberty, growth retardation, diabetes mellitus, hypoparathyroidism, and eventually liver cirrhosis and cardiac failure. These complications can be delayed and possibly prevented by the early administration of an iron chelator.

Two iron chelators are available in North America. The first, deferoxamine (Desferal), is administered by a battery-powered pump as a daily 12-hour subcutaneous infusion. It has been the main chelator used for the past 4 decades. Deferasirox (Exjade) is an effective oral iron chelator in patients with iron overload and is approved for children older than 2 years of age. The initial dose is 20 to 30 mg/kg/ by mouth once daily. In a randomized trial of Desferal versus Exjade in patients with transfusional iron overload, the two chelators showed similar efficacy. In an international multicenter study in which the efficacy of Exjade was assessed in patients with anemia of various etiologies, 30 patients with DBA were included. Successful chelation was observed in 54% of the DBA patients as defined by reduction of liver iron concentration by biopsy to less than 7 mg/g dry weight within 1 year. Given its oral route of administration, it is predicted that Exjade will replace Desferal as the iron chelator of choice.

There are uncertainties about the optimal age at which to start patients younger than 2 years old with transfusion-dependent anemia with desferal therapy. There have been reports of abnormal linear growth and metaphyseal dysplasia in patients with thalassemia major treated with Desferal before the age of 3 years. This adverse event has prompted recommendations for starting Desferal later. However, a progressively rising serum ferritin level or, more accurately, excessive hepatic iron concentration obtained by biopsy after 1 year of regular transfusions would be an appropriate indication to commence chelation therapy. The daily starting subcutaneous infusion dose of Desferal should not exceed 50 mg/kg. Ascorbate supplementation should be considered if there is sustained loss of efficacy of deferoxamine, especially if tissue ascorbate concentrations are reduced.

Corticosteroids

Steroid responsiveness occurs in 50% to 75% of DBA patients. Upon administration of prednisone at a dose of 2 mg/kg/day in three divided doses, reticulocytosis is usually seen within 1 to 4 weeks and is followed by a rise in hemoglobin concentration. When the hemoglobin level reaches 9.0 to 10.0 g/dL, prednisone can be slowly tapered by reducing the number of daily doses. If a single daily dose of prednisone maintains the desired hemoglobin level, the dose can be doubled and given on alternate days, but this may not prevent significant steroid toxicity.

The dose of prednisone can be further reduced by small decrements on a weekly basis or more slowly until the minimal effective dose is determined. This dose is extremely variable. A few patients can be maintained on minute, nonpharmacologic doses, but other patients need large doses that preclude long-term therapy because of serious side effects such as Cushingoid features, pathologic fractures, cataracts, growth failure, diabetes, and avascular necrosis of the femoral or humeral heads. There is no known predictor of steroid responsiveness or any way to anticipate the type of individual responses. In general, a corticosteroid dose equivalent of prednisone, 0.5 mg/kg/day, is suggested as a maximum "maintenance" dose after the initial dose of 2 mg/kg/day. About one-third of patients can maintain a response at a low prednisone dose. The rest are usually managed with chronic RBC transfusions.

There are several patterns of response to corticosteroid therapy, some of which may occur at different times in the same patient. Most children who respond to steroids cannot be completely weaned off the medication and become steroid dependent. About one-third of these patients, however, enter steroid-free remission after a prolonged period of treatment. Between 1% and 5% of responders immediately enter a durable steroid-independent remission. However, late relapses, sometimes precipitated by an infectious illness or by hormonal changes such as in pregnancy or with the use of birth control pills, are common. In other cases, a progressive resistance to steroids occurs, requiring escalating doses of prednisone or alternative therapy. After a relapse, some patients are responsive to steroids again, but others are refractory to subsequent trials. Initial refractoriness to steroids is observed in 36% of cases. In more than 60% of patients, long-term steroid therapy is hampered by the development of resistance or by side effects of the treatment. In adolescent responders on long-term steroids, an option is to stop prednisone temporarily to allow a

normal growth spurt. Infants with DBA on high doses of steroids are at risk for pneumocystis pneumonia and should be given prophylactic antibiotics.

High-Dose Methylprednisolone. Megadose steroid therapy for DBA patients who were refractory to conventional-dose prednisone has been reported to induce a sustained erythroid response leading to transfusion independence in 8 of 13 cases. Eleven had been treated with 100 mg/kg/day intravenously, and two additional patients had been treated with 30 mg/kg/day orally. Another report showed only a transient response in one of eight patients after intravenous treatment with 30 mg/kg/day and a sustained response after a higher dosage (100 mg/kg/day) in three of eight patients, but side effects were weight gain, oral moniliasis, increase in hepatic transaminases, transient hyperglycemia, and bacteremia related to a central venous catheter. A conclusive study of nine refractory DBA patients using megadose oral methylprednisolone showed no response in five cases and a partial or complete response in the other four during the initial 4 to 8 weeks of therapy, but all of these patients relapsed with a taper and became transfusion dependent. Thus, none of the cases exhibited a clinically significant or durable response.

Cytokine Therapy

Because of the "corrective" effect on erythropoiesis by IL-3 in vitro, clinical trials were introduced for steroid-refractory and steroid-dependent DBA patients and for those in whom HSCT was considered too risky. The early enthusiasm generated by sustained remissions in some patients was tempered by the realization that IL-3 is effective in only a very small number of cases of steroid-refractory, transfusion-dependent DBA. Of 49 patients treated with IL-3 in a European multicenter compassionate-need study, only three children had a significant response with sustained remissions off therapy. A comparison of individual patient characteristics confirmed that patients who had never achieved significant in vivo erythropoiesis in response to steroids or during a spontaneous remission were highly unlikely to respond to IL-3. Thus, the overall response rate in all published studies averaged 10% to 20%. Currently, there are no IL-3 or other growth factor clinical trials in North America for DBA. Serum erythropoietin levels are elevated in DBA, and attempts at treatment with high-dose erythropoietin have been ineffective.

Hematopoietic Stem Cell Transplantation

Hematopoietic stem cell transplantation is a therapeutic option for DBA, but the risks must be weighed against the benefits on a case-by-case basis. The fundamental issue centers on the defined mortality rate with HSCT when used for a nonlethal medical disorder, at least a disorder that is nonlethal in the short term. In steroid-responsive patients on low-dose maintenance and in properly transfused and adequately chelated patients, quality of life is not threatened by life-threatening complications. Thus, the decision for intervention with HSCT in this setting is difficult.

Nevertheless, experience has broadened since the first HSCT was performed for DBA in 1976. Preparative regimens, supportive measures, and GVHD management have progressively become more refined, thereby reducing the overall risks of the procedure. For consideration in the decision-making process, though, there are still lethal risks, including interstitial pneumonia, cardiac failure, fatal complications associated with chronic GVHD, graft failure, graft rejection, and sepsis. Results from the International Bone Marrow Transplant Registry show a 64% 3-year probability of overall survival of 61 transplanted DBA patients. The DBAR and the Aplastic Anemia Committee of the Japanese Society of Pediatric Hematology report an 87.5% and an 85% survival, respectively, but express caution that alternative donors pose a much higher risk than matched sibling donors. From the DBAR database, the survival rate for patients younger than the age of 10 years receiving matched related HSCT is greater than 90%. Related and unrelated umbilical cord blood as a stem cell source has been used for DBA HSCT with favorable results. Given the generally favorable results with related donors, this procedure can now be offered to patients approximately after the age of 5 years when no spontaneous remission is apparent. However, HSCT from an unrelated donor is not recommended unless the patient has severe aplastic anemia, MDS, or leukemia or as part of a clinical trial.

This success with related donors has sparked interest in PGD with in vitro fertilization to "create" HLA-matched sibling donors without a mutated DBA gene, and a number of patients worldwide have been successfully transplanted using umbilical cord–derived stem cells from donors produced in this way. The religious, ethical, and economic questions generated by PGD to find a healthy matched donor for DBA and other inherited BM failure transplantations is ongoing.

Other Therapeutic Options

Based on the role of the DBA genes in ribosome biogenesis and global protein translation and in vitro studies aimed to stimulate translation in BM cells, a trial was performed in which the branched amino acid leucine was administered to a patient with DBA patient. The patient had an impressive response. Based on this, two leucine trials are ongoing in the United States and Europe. Leucine stimulates translation by enhancing the activation of translation initiation factors that regulate mRNA binding to the ribosomal complex and by activation of the ribosomal protein S6 kinase and the mTOR (mammalian target of rapamycin) pathway.

A number of uncontrolled therapeutic trials have been performed in steroid-refractory patients using various medications and treatments with varying anecdotal successes in a few patients. The medications include cyclosporine, metoclopramide, lenalidomide, androgens, riboflavin, vitamin B_{12}, folate, iron and other "hematinic" agents, 6-mercaptopurine, cyclophosphamide with antilymphocyte globulin, and antithymocyte globulin alone. There is a case report claiming efficacy of valproic acid for DBA and another report of an 8-month transfusion-free remission after rituximab therapy. Plasmapheresis has also been tried. Splenectomy, used in the past, shows no effect on erythropoiesis but may be helpful in transfused patients with proven hypersplenism.

Future Directions

Registries and DBA patient databases will continue to broaden our understanding of the genetic origins and epidemiology of DBA. Specimen collection and distribution to qualified research laboratories globally will identify the remaining DBA genes. Genetically based DBA diagnosis and pedigree analysis will underscore the broad dimensions of the DBA phenotype, from clinically silent to life-threatening severe. Genotype–phenotype correlations will facilitate HSCT donor selection, allow counseling for reproductive options, and be predictive of cancer risk. Deciphering the pathogenesis of BM failure and other disease manifestations using animal models and iPSCs may allow the development of effective erythropoietic stimulators for use in this disease.

Kostmann Syndrome and Severe Congenital Neutropenia

Background

Kostmann syndrome and SCN refer to inherited types of neutropenia with onset in early childhood of profound neutropenia (ANC <200/μL), recurrent life-threatening infections, and a maturation arrest of myeloid precursors at the promyelocyte-myelocyte stage of differentiation. Some experts in the field refer to KS as the autosomal recessive type of severe inherited neutropenia and to SCN to all the other inherited neutropenia with similar phenotype. However, because many IBMFSs are inherited in different modes and because

SCN and KS are indistinguishable phenotypically in the majority of the patients, the option to "split" the two disorders is debatable. In this chapter, we will refer to them as K/SCN.

The initial description of syndrome made by Dr. Kostmann in 1956 included several neutropenic patients in a large intermarried Swedish kinship. An autosomal recessive mode of inheritance in 24 cases was deduced by inference because of hematologically normal parents with two or more neutropenic children in several families. Recently, homozygous germline *HAX1* mutations have been identified in patients with KS, including some from Kostmann's original pedigree, confirming an autosomal recessive inheritance in these families. Nevertheless, it is now clear that K/SCN are genetically heterogeneous despite a shared hematologic phenotype (see Table 27-1). The first identified K/SCN gene was the neutrophil elastase 2 gene *(ELA2),* which was found mutated one one allele in patients with K/SCN, indicating an autosomal dominant inheritance in many cases.

Epidemiology

K/SCNs are rare. The estimated incidence based on Canadian data from CIMFR from 2001 to 2010 was 4.7 cases per million live births per year. There is equal distribution of the disease between genders. There might be different frequency of specific genetic groups in different countries. For example, no *HAX1* mutations were found among cases from the United States or Canada.

Etiology, Genetics, and Pathophysiology

The discovery of heterozygous mutations in the *ELA2* gene encoding neutrophil elastase in 22 of 25 sporadic and dominantly inherited patients with K/SCN was the entry point for understanding the molecular basis of the disorder in many patients. As experience with genetic testing has broadened, it appears that 60% to 80% of cases have spontaneously occurring or inherited point mutations in *ELA2* and, less commonly, mutations in other genes. Mutant *ELA2* also occurs in all cases of classical cyclic neutropenia, but the mutations cluster in exon 4 or 5 on the gene on chromosome 19p13.3 or at the junction of exon 4 with intron 4. Patients with congenital neutropenia have mutations more widely distributed over exons 2, 3, 4, and 5.

Although typical K/SCN patients present early in life with severe neutropenia and life-threatening infections, rare cases with *ELA2* mutations in phenotypically healthy family members were reported. For example, two siblings with congenital neutropenia inherited the same heterozygous ELA2 mutation from their hematologically normal father. In another family, a healthy father of a congenital neutropenia patient was mosaic for his daughter's Cys42Arg mutation in peripheral blood hematopoietic cells. The mutation was found in about 50% of his T lymphocytes but only in 10% of his neutrophils. This is congruent with a lack of recurrent infection phenotype in the father. The mutation was evident in myeloid precursors but was selectively lost during myelopoiesis or failed to mature to neutrophils.

The exact mechanism whereby mutant *ELA2* causes neutropenia is under intense study. *ELA2* encodes neutrophil elastase; a glycoprotein synthesized in the promyelocyte/myelocyte stages and packed in the azurophilic cytoplasmic granules. It is released in response to infection and inflammation. The wild-type neutrophil elastase diffusely localizes throughout the cytoplasm, but the mutated protein in cases of congenital neutropenia abnormally concentrates in the nucleus and plasma membrane. There are several lines of evidence that mutant ELA2 protein triggers accelerated apoptosis of developing neutrophil precursors. Mutant protein leads to accumulation of nonfunctional protein in the endoplasmic reticulum, activation of unfolded protein response, and apoptosis of K/SCN neutrophils. In addition, decreased expression of Bcl-2 was observed in K/SCN myeloid progenitor cells along with constitutive mitochondrial release of cytochrome C and excessive cellular apoptosis. Of note, administration of G-CSF restored Bcl-2 expression and improved survival of myeloid progenitor cells. Another proposed mechanism is downregulation of lymphoid enhancer-binding factor 1 (*LEF-1*) in K/SCN. This leads to reduced transcription of *LEF1*-target genes such as *C/EBP-α* and impaired granulocytic differentiation.

HAX1 was reported to be mutated in 40% of patients with K/SCN in a European study but in none of the patients in the American studies and in none of the patients in the Canadian Inherited Marrow Failure Study. HAX1 localizes to the mitochondria. It contains two domains reminiscent of a BH1 and BH2 of the BCL-2 family. It promotes normal potential of the inner mitochondrial membrane and protects myeloid cells from apoptosis. The direct function of HAX1 in promoting survival may explain the accelerated apoptosis reported in K/SCN neutrophils. *HAX1-mutant* K/SCN cells are also characterized by reduced LEF1 levels as in *ELA2-mutant* K/SCN cells.

A constitutively activating mutation in the Wiskott-Aldrich syndrome protein encoded by the *WASP* gene was discovered in five males from a three-generation family. The phenotype of the resulting X-linked immunodeficiency syndrome was composed of severe neutropenia from birth, bacterial infections, monocytopenia, and shifts of lymphocyte subsets. BM morphology showed a selective maturation arrest at the promyelocyte/myelocyte stage similar to K/SCN. Mutant *WASP* leads to constitutive activation of the WASP protein because of disruption of an autoinhibitory domain in the wild-type protein. This increased WASP protein activity produces marked abnormalities of cytoskeletal structure and dynamics, disruption of mitosis, genomic instability, and apoptosis of neutrophils.

Mutations in the proto-oncogene *GFI1* also cause K/SCN with severe neutropenia and a maturation arrest at the promyelocyte–myelocyte stage. GFI1-deficient mice exhibit severe neutropenia with accumulation of abnormal arrested progenitors and increased HSC/P proliferation. GFI1 is a transcriptional repressor of several transcription programs. The first transcription program is active during the progenitor stage. During this stage, GFI1 downregulates the HoxA9-Pbx1-Meis1 transcription factor complex. Because HOXA9 drives progenitor proliferation, GFI1 deficiency leads to uncontrolled HOXA2 activation and accumulation of arrested-differentiation myeloid progenitors. The second transcription program is activated during terminal granulopoietic differentiation. During this stage, GFI1 represses genes that promote differentiation of nongranulocytic cells such as CSF1. Patient-related mutations also disable the GFI1 repressor activity on *ELA2* expression, which leads to accumulation of neutrophil elastase in all subcellular compartments and might underlie the mechanism for premature apoptosis. Another potential mechanism for neutropenia when GFI1 is deficient might be related to loss of GFI1-mediated regulation of the expression of the micoRNAs miR-21 and miR-196b, which regulate myeloid maturation.

A constitutive point mutation was discovered in the extracellular domain of the G-CSF receptor in a patient with K/SCN who also had a mutant *ELA2* gene. The receptor mutation affected ligand–receptor complex formation with severe consequences for intracellular signal transduction; the patient was totally unresponsive to G-CSF therapy. As demonstrated in vitro and then clinically, corticosteroids combined with G-CSF produced a corrective action through synergistic activation of STAT5, and the patient responded to G-CSF therapy. Three subsequent patients with cell-surface G-CSF receptor mutations were also refractory to G-CSF therapy and suggest that this may be a common finding in cases unresponsive to treatment.

Regarding the cellular pathology of K/SCN, many cell culture studies performed in the 1970s and 1980s provided clonogenic data that pointed to intrinsically defective granulocytic progenitors. Further reports confirmed this and excluded other possible pathogenetic factors. To summarize: (1) K/SCN BM myeloid colony growth is defective, (2) K/SCN serum contains normal or increased levels of G-CSF, (3) endogenous K/SCN G-CSF has normal biologic activity,

(4) G-CSF receptors are expressed in slightly increased numbers on myeloid cells from K/SCN patients, and (5) the binding constant for G-CSF to its receptor in K/SCN is normal.

Regarding correlation between the mutated gene and phenotype, *ELA2* mutations are associated with severe and early-onset neutropenia with differentiation arrest at the stage of promyelocyte-myelocyte. Typically, the patients do not have physical malformations. The patients have a high risk of MDS/AML but no known risk of solid tumors. Patients with mutations in *HAX1* typically have severe and early-onset neutropenia with differentiation arrest at the stage of promyelocyte–myelocyte. They also have a high risk of MDS/AML but no known risk of solid tumors. About 30% of the patients with *HAX1* mutations have neurologic abnormalities such as seizures, learning disabilities, and developmental delay. This is usually attributable to nonsense mutations (e.g., p.Gln155ProfsX14) that affect both *HAX1* transcripts. Mutations in *WAS* are associated with moderate to severe neutropenia, reduced phagocyte activity, monocytopenia, lymphopenia, reduced NK cells, reduced lymphocyte proliferation, and recurrent infections (but usually not as frequent as in the classical K/SCN). MDS/monosomy 7 has also been reported. *GFI* mutations are associated with severe to moderate neutropenia, and monocytosis, reduced B and T cells with normal lymphocytic function. There are no clear data about the BM findings in this type of neutropenia, and the risk of MDS/AML is unknown.

Clinical Features

Approximately half of patients develop clinically significant infections within the first month of life and almost all others develop them by 6 months. Skin abscesses are common, but deep-seated tissue infections and septicemias also occur. Data from the SCNIR illustrate examples of every conceivable form of bacterial and fungal infection in the precytokine era. Especially troublesome in survivors were recurrent episodes of otitis media and pneumonia; advanced gingival stomatitis, sometimes with tooth loss; and in the extreme, gut bacterial flora overgrowth, leading to malabsorption requiring total parenteral nutritional therapy.

In contrast to some of the other IBMFSs, physical malformations are uncommon. Birth weights are generally unremarkable, and physical examination findings are usually normal. There are a small number of reports of short stature, cataracts, microcephaly, seizures, developmental delay, and mental retardation. As mentioned earlier, neurologic manifestations are part of a small group of patients with *HAX1* mutations. Data from the SCNIR indicate that some patients with K/SCN develop bone demineralization that may be an intrinsic component of the disorder; it has been observed before and during G-CSF therapy. The underlying pathogenesis is unclear, but patients can develop bone pain and unusual fractures. Osteopenia is a common theme with the IBMFSs.

Laboratory Findings

Peripheral Blood and Bone Marrow

Neutropenia is profound and persistent in K/SCN, usually less than 200/μL. A small number of patients have intermittent cycling patterns with regular periodicity that ranges in a low to severely low neutrophil count range. A compensatory two- to fourfold increase in monocytes is seen, sometimes accompanied by eosinophilia. At diagnosis, platelet numbers are normal or increased, and hemoglobin values are usually normal. In survivors in the precytokine era, anemia of chronic disease associated with recurrent infections and inflammation was common. Aside from neutropenia, humoral and cellular immunity is completely normal.

Bone marrow specimens are usually normocellular. The striking classical finding is a maturation arrest at the promyelocyte or myelocyte stage with a paucity of more mature elements. Promyelocytes are abundant and may have atypical nuclei and the cytoplasm may be vacuolated. Neutrophils and bands are usually absent (Fig. 27-11). BM eosinophilia and monocytosis is common. The other hematopoietic lineages are normal, active, and undisturbed.

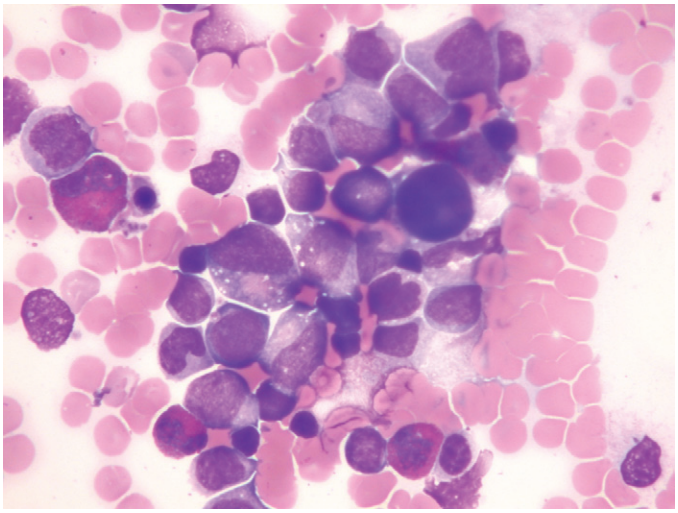

Figure 27-11 HIGH-POWER VIEW OF A BONE MARROW ASPIRATE FROM A PATIENT WITH KOSTMANN SYNDROME (CONGENITAL NEUTROPENIA) BEFORE GRANULOCYTE COLONY-STIMULATING FACTOR THERAPY. The findings are a "maturation arrest" with recognizable myeloblasts, promyelocytes, myelocytes, and occasional metamyelocytes but total absence of band forms and neutrophils. *(Photomicrograph prepared by Dr. Mohamed Abdelhaleem, Toronto.)*

Predisposition to Leukemia and Myelodysplastic Syndrome

Clearly, K/SCN carries a high risk of leukemia. There were three case reports of patients who developed AML before the use of hematopoietic growth factors and one more recent patient diagnosed with acute leukemia before starting G-CSF. As a rough estimate, in the literature, there were 128 cases of congenital neutropenia reported and three cases of AML up to 1989 (the first year that G-CSF was available for general use), leading to a crude estimated risk of leukemia of 2%. Nevertheless, because most patients with congenital neutropenia died at a young age from bacterial sepsis or pneumonia in the precytokine era, the true risk of patients with congenital neutropenia developing MDS/AML was not clearly defined.

G-CSF therapy completely changed clinical outcomes of K/SCN. Before G-CSF, the median duration of survival was about 3 years; the current median age is more than 40 years. The number of documented cases of MDS/AML has dramatically increased since 1989, which likely reflects the natural history of the disease that is now allowed to manifest by prolonging life. However, whether G-CSF increases this risk or hastens the appearance of leukemia is still debatable. From 1987 to year-end 2005, data at the SCNIR identified 50 of 422 patients with K/SCN who developed MDS/leukemia (crude rate of 11.8%).

To determine if the incidence of MDS/AML in the SCNIR patients is related to G-CSF dosage or duration of therapy or to other patient demographics, a detailed analysis was conducted on 374 patients who received G-CSF for at least 10 years. After 10 years on G-CSF, the annual risk of MDS/AML was stable at 2.3% per year. After 15 years on G-CSF, the cumulative incidence of MDS/AML was 22%.

The risk of MDS/AML is higher in patients requiring higher doses of G-CSF. According to SCNIR data, less responsive patients, defined as those having ANCs of less than 2.1×10^9/L on G-CSF doses greater than 8 μg/kg/d had a cumulative incidence of MDS/AML of 34% after 15 years; more responsive patients, defined as having ANCs

of greater than 2.1 $\times 10^9$/L on G-CSF doses lower than 8 μg/kg/d had a cumulative incidence of 15%. The data were interpreted as indicating that a poor response to G-CSF defines an "at-risk" population and predicts an adverse outcome. The data do not necessarily support a cause-and-effect relationship between development of MDS/AML and G-CSF therapy. The results may only mean that patients requiring higher G-CSF therapy have a more severe clinical and hematologic phenotype. A report from the French Severe Chronic Neutropenia Study Group confirmed that increased exposure to G-CSF with respect to dose and duration in congenital neutropenia patients was associated with a heightened risk of MDS/AML, but they do not speculate on the mechanism.

Conversion to MDS/AML in K/SCN patients is associated with one or more cellular genetic abnormalities that provide insight into the pathobiology of the transformation and may be useful in identifying patients who are at high risk. Several cellular and genetic changes have been found in the BM of patients with K/SCN who received G-CSF. Whether these changes are coupled to G-CSF therapy is unknown. Remarkably, the abnormalities have predictable, similar characteristics in most patients and underscore a fairly specific multistep pathogenesis in the evolution into MDS/AML. At varying time points after starting G-CSF therapy, about half of the congenital neutropenia patients who transform acquire the same activating RAS oncogene mutation, namely a GGT (glycine) to GAT (aspartic acid) substitution at codon 12. More than 90% of patients who transform also show an acquired cytogenetic clonal alteration in BM cells, usually −7 or 7q- but also +21 or +8. Complex cytogenetics (e.g., −7 and +21) have also been identified. More than 80% of patients develop one or more G-CSF receptor point mutations. These G-CSF-R mutations are nonsense mutations that result in the truncation of the C-terminal cytoplasmic region, a subdomain that is crucial for G-CSF–induced maturation. The acquired mutation is directly operative in the conversion to MDS/AML. In murine models, the mutation results in impaired ligand internalization, defective receptor downmodulation, and enhanced growth signaling that produces an exaggerated hyperproliferative effect in response to G-CSF. This also confers resistance to apoptosis and enhances cell survival that favors clonal expansion in vivo. The detection of G-CSF-R mutations places patients at high risk for malignant conversion, but the time course from detection of mutations to overt MDS/AML varies considerably and may take years.

Although patients requiring higher doses of G-CSF to attain safe neutrophil levels are at a higher risk of developing MDS/AML, there is no definitive evidence that G-CSF directly causes malignant transformation. G-CSF may simply be an "innocent bystander" that corrects the neutropenia, prolongs patient survival, and allows time for the malignant predisposition to declare itself. Alternatively, G-CSF may accelerate the propensity for MDS/AML in the genetically altered stem and progenitor cells in congenital neutropenia. G-CSF may rescue malignant clones that would otherwise be destined for apoptosis. The clinical interplay between G-CSF and the receptor mutation was underscored in the report of a patient with congenital neutropenia on G-CSF who developed a receptor mutation and AML. When G-CSF was stopped, the blast count in blood and in BM fell to undetectable levels on two occasions without giving chemotherapy, although the mutant receptor was persistently detectable during the remissions. A similar patient has been observed in Toronto (Y. Dror, unpublished data).

An axiom of oncogenesis is that rapidly dividing cells are more susceptible to mutational events. Because therapeutic G-CSF provides a powerful proliferative signal for BM cells, it is a reasonable hypothesis that congenital neutropenia BM progenitors acquire new mutations. From the evidence cited herein, acquisition of a G-CSF receptor mutation in the face of therapeutic G-CSF in congenital neutropenia can provide the hyperresponsive replicative scenario that can relentlessly evolve into MDS/AML. Is recombinant human G-CSF a carcinogen? This would seem highly unlikely. As a physiologic regulator of hematopoiesis, it would be unexpected for G-CSF to break molecular bonds and cause DNA damage even when used in therapeutic dosages.

Differential Diagnosis

The commonest cause of isolated neutropenia in very young children is **viral-induced BM suppression.** An antecedent history of good health, the occurrence of a viral illness, and the transient nature of the neutropenia distinguish this disorder from K/SCN.

Autoimmune neutropenia of infancy is recognized as a fairly specific syndrome of early childhood. Low neutrophil numbers are often discovered during the course of routine investigation for a benign febrile illness. The illness abates, but the neutropenia persists, sometimes for months and occasionally for years. A BM biopsy is normocellular, and an aspirate shows active granulopoiesis up to the band stage; neutrophils may be normally represented, reduced or absent. The neutropenia is caused by increased peripheral destruction and the diagnosis can be supported by demonstrating specific antigranulocyte antibodies on neutrophils. The prognosis is good, the neutropenia is self-limited albeit protracted, and patients seldom develop serious bacterial infections as a result of it. Other infrequent acquired causes of severe, isolated neutropenia in this age group include BM suppression from a drug or toxin and neutrophil sequestration as part of a hypersplenism syndrome.

Of the IBMFSs, **SDS** can also manifest as isolated neutropenia but can be identified because of growth failure, the malabsorption component caused by pancreatic insufficiency, fatty changes in the pancreas seen on CT scanning or ultrasonography, and characteristic skeletal abnormalities. **Glycogen storage disease type 1b (GSD-1b)** and **Barth syndrome** are also in the differential diagnosis. Neutropenia can also be a prominent part of **antibody deficiency syndromes** and **cellular immunodeficiency disorders** (Table 27-8); investigation of chronic neutropenia of childhood should include an immunoglobulin electrophoresis, T-cell proliferative studies, and quantitation of T-cell subsets and NK cell activity. **Cyclic neutropenia** is distinguished by predictable symptomatology, especially mouth sores about every 3 weeks (19-23 days), often associated with chronic gingivitis. A complete blood count two or three times a week for 4 to 8 weeks demonstrates the diagnostic oscillation pattern with a cyclic nadir. Other **unclassified inherited neutropenia syndromes** with vertical transmission or in siblings have been described. The neutropenia in such cases are typically mild to moderate. When severe **neutropenia is diagnosed in the newborn period,** the cause may be passive transfer transplacentally of IgG antineutrophil antibodies from the mother. This can occur if the mother has an autoimmune disorder with neutropenia or by alloimmunization caused by fetomaternal incompatibility for a neutrophil-specific antigen.

Therapy and Prognosis

Before the introduction of G-CSF as a specific therapy of K/SCN, there was limited treatment. Antibiotics were the mainstay of management for active infection and for prophylaxis. Attempts to mobilize neutrophils with lithium had limited application.

Cytokine Therapy

G-CSF has supplanted all other forms of management because more than 90% of K/SCN patients respond. It is recommended to begin G-CSF therapy as front-line treatment when the diagnosis is established. GM-CSF in crossover trials with G-CSF for K/SCN is not as effective and does not induce a neutrophil response consistently. If the ANC remains below 1.0×10^9/L after initiation of G-CSF at 5 μg/kg/dose once a day subcutaneously, the dose may be escalated to 10 μg/kg/dose and then by increments of 10 μg/kg/dose at 14-day intervals until a response is seen. As soon as the ANC can be maintained at 1.0×10^9/L or above, the G-CSF dose does not have to be increased further because the occurrence of bacterial infection is reduced dramatically with an ANC at this level. Patients who are proven to be infection free with ANC of 0.75 to 1.0 may continue on the same G-CSF doses. The G-CSF dose can be reduced if the ANC increases to 5.0×10^9/L or above to find the lowest dose

Table 27-8 Miscellaneous Inherited Neutropenia Disorders

Diagnosis	Genetics	Mapping	Mutant Gene	Additional Features
Hyper IgM syndrome, type 1	X-L	Xq26	*CD40L*	↓IgG, IgA, IgE, autoimmune cytopenias
Hermansky-Pudlak syndrome, type 2	AR	5q14.1	*AP3B1*	↓IgG, partial albinism, platelet dysfunction
Griscelli syndrome, type 1	AR	15q21	*MYO5A*	Neurologic dysfunction, partial albinism
Griscelli syndrome, type 2	AR	15q21	*RAB27A*	Same as type 1 plus hemophagocytosis
Chediak-Higashi syndrome	AR	1q42.1-q42.2	*LYST (CHSI)*	Immunodeficiency, partial albinism
Poikiloderma with Neutropenia	AR	16q13	*C16ORF57*	Rash, short stature, dystrophic nails
P14 deficiency	AR	1q22	*MAPBPIP*	Immunodeficiency, hypopigmentation
Cohen syndrome	AR	8q22-q23	*VPS13B/COH1*	Retinopathy, retardation, skeletal anomalies
Charcot-Marie-Tooth syndrome, type 2	AD	19p13.2	*DMN2*	Axonal demyelinating neuropathy

necessary for maintaining a neutrophil count at 1.0×10^9/L or greater. The SCNIR co-investigators defined nonresponders as patients who do not respond to G-CSF levels exceeding 120 μg/kg/day. Partial responders show an increase of their ANC to 0.5 to 1.0×10^9/L with the highest dose, but they still experience bacterial infections. In these patients, the dose of G-CSF cannot be increased because of the large volume and frequency of injections required. In some of these patients, a combination of G-CSF with SCF can induce a further increase in the ANC, but the potential allergic side effects of SCF have limited the use of this treatment combination to hospitalized patients with severe infections who also receive concomitant antihistamines. The only currently available treatment for patients who do not respond to G-CSF treatment alone or in combination with SCF is HSCT. In one published case of a G-CSF nonresponder, the addition of small dose of prednisone (5 mg/day) to a standard G-CSF dose of about 5 μg/kg resulted in a long-term complete response.

All patients on G-CSF therapy should be seen by a physician every 3 to 6 months. Patients requiring more than 8 μg/kg/day are at higher risk for MDS/AML and should be evaluated more often. Blood counts (white blood cells, hemoglobin, platelets, and differential blood counts) should be obtained and a physical examination performed at least every 3 months, including assessment for weight and height in pediatric patients and documentation of intercurrent infections. BM examination for morphology and cytogenetics is recommended once a year to search for acquired cytogenetic abnormalities such as monosomy 7 or trisomy 21.

From SCNIR data, a sustained hematologic response in patients treated with G-CSF for more than 15 years has been confirmed. With therapy, neutrophil counts rise in more than 90% of K/SCN patients and are maintained at a plateau for protracted periods, resulting in vast clinical benefits. In no instance has there been BM or hematopoietic lineage "exhaustion" or depletion with G-CSF therapy.

Hematopoietic Stem Cell Transplantation

The SCNIR transplant data was reported in 2000. Of 29 who were transplanted, 18 had transformed to MDS, AML, or both, and the dual goal was to cure the malignancy and the neutropenia. Only three of the 18 were successful. The causes for failure included mismatched transplants, progressive refractory AML, serious illness at the time of the procedure, and transplants performed in desperation. The other 11 patients underwent HSCT for reasons other than malignant transformation, mostly because of no response or only partial response to G-CSF. Eight patients received stem cells from an HLA-matched sibling after conditioning mainly with busulfan–cyclophosphamide alone or with additional immunosuppression. In sharp contrast to the MDS/AML group, nine of the 11 were cured with resolution of neutropenia.

A summary of 18 K/SCN cases transplanted between 1989 and 2005 in Japan for lack of or a partial response to treatment with G-CSF but without MDS/AML was published in 2010. Nine patients received stem cells from an HLA-identical sibling donor and nine from an alternative donor. Twelve received myeloablative regimens, and 6 patients received varying nonmyeloablative conditioning regimens. Sixteen of the patients were reported alive and in complete remission at a median follow-up of 6.5 years.

A multicenter retrospective analysis of umbilical cord transplants for IBMFs in Europe published in 2011 included 16 patients with K/SCN. The conditioning regimens were myeloablative in nature. One patient received a related cord blood graft, and the other 15 received unrelated grafts. Three patients were transplanted for leukemia or MDS using unrelated cord blood; two died. The other 13 patients were transplanted because of a lack of response to G-CSF. At a median follow-up of 41 months, 11 of the 13 were alive; one received an untreated graft, and 10 received unrelated grafts.

In the literature, seven patients received nonmyeloaplastive regimens. However, the small number of patients, the different regimens, and the different indications (refractoriness to G-CSF or MDS/AML) do not allow meaningful conclusions.

In general, the best scenario for a curative HSCT is when the procedure is performed before developing MDS/AML using a matched-related donor and when the patient is in good physical condition. In a small series of six transplanted patients for MDS or AML, two with MDS who underwent the procedure without being given induction chemotherapy survived, but four with AML given induction chemotherapy had significantly more morbidity and died posttransplant, raising questions about conditioning strategies for these patients.

The discovery of an isolated BM clonal cytogenetic abnormality without other evidence of MDS or AML in patients with congenital neutropenia raises management issues. One option is to perform HSCT if there is a matched donor as soon as feasible. This has generally been recommended for patients with −7, 7q-, or +21. The a priori argument is that the chance for cure is higher when the patient is well and has a low burden of malignant cells. The problem with this decision centers on not knowing the tempo of progression from cytogenetic evolution to clear-cut MDS or AML. Thus, there may not be a need to rush to transplant in all patients. Instead, one recommendation is to lower the G-CSF to the lowest dose that maintains neutrophil counts greater than 0.5×10^9/L and to monitor the patient regularly with blood counts and by serial BM testing.

Opinions also vary about the best way to manage patients with other genetic changes such as *G-CSF-R* or *RAS* mutations but without clonal BM cytogenetic abnormalities or morphologic evidence of transformation. In one patient with an isolated G-CSF receptor

mutation, an HSCT was performed to eliminate the risk of leukemic conversion. Debate about this approach continues, and watchful waiting is an acceptable option.

Bisphosphonates for Osteoporosis

In 50% of K/SCN patients on G-CSF, bone density measurements show varying degrees of osteopenia and osteoporosis. Most of these are subclinical and asymptomatic, but some patients complain of bone pain and have fractures. Evidence shows that bisphosphonates are effective treatment for the majority of these cases.

Future Directions

The list of K/SCN genes is by no means complete, and further studies are necessary to discover novel genes. It is also not clear if there is an association between specific mutations and the risk of evolution to MDS and acute leukemia, but studies are ongoing to try to answer this clinical question. At present, diagnosis of cyclic and congenital neutropenia still depends primarily on observations of serial blood cell counts, but it is expected that mutational analysis of the *ELA-2* gene will become a routine part of making the diagnosis and the establishment of a prognosis for these patients in the years ahead. Because apoptosis is a central mechanism of neutropenia in these patients, future studies will determined whether the term *maturation arrest* should be replaced by *accelerated apoptosis* as a descriptive term for the BM findings. It appears that cellular models involving transfection of the mutant genes into human myeloid cell lines provide evidence of how neutropenia occurs. Potentially, these models can also be used to examine new approaches to preventing apoptosis and serve to provide clues to new and more effective therapies. Considerable data now confirm the effectiveness of G-CSF in the treatment of various forms of K/SCN. However, the inconvenient administration, potential long-term effects, and lack of response in 10% of the patients require the development of alternative therapies.

Other Inherited Neutropenia Syndromes

Barth Syndrome

Barth syndrome is a rare multisystem metabolic disorder inherited in an X-linked recessive mode. It is the first human disease in which the primary causative factor is an alteration of cardiolipin remodeling. Cardiolipin is a component of the inner mitochondrial membrane necessary for proper functioning of the electron transport chain. The findings in typical cases are mild to severe neutropenia, dilated or hypertrophic cardiomyopathy, underdeveloped skeletal musculature and muscle weakness, exercise intolerance, growth delay, cardiolipin abnormalities, and 3-methylglutaconic aciduria. ANCs are variable, but total agranulocytosis has been reported. BM morphology includes a maturation arrest at the myelocyte stage. On electron microscopy, mitochondria show concentric, tightly packed cristae and occasional inclusion bodies in various tissues, including granulocyte precursors. Clinically, the cardiomyopathy dominates the clinical picture, but gingivitis, oral problems, and bacterial sepsis from neutropenia can be problematic. Anecdotal reports and the authors' experience (Y. Dror, unpublished data) suggest that G-CSF is highly effective in correcting the neutropenia and preventing infections. The myriad of clinical problems requires a multidisciplinary approach. Female carriers are healthy and hematologically normal, likely because of extreme skewing of X-inactivation. The initial impression that Barth syndrome was a lethal infantile disease has been modified; age distribution in 54 living patients ranges from 0 to 49 years and peaks around puberty.

The Barth syndrome gene was mapped to Xq28, which led to the cloning of the *TAZ* gene and the various mutations that account for the phenotype. *TAZ* produces several different mRNAs with resultant proteins called tafazzins. Mutations in *TAZ* result in a decrease in tetralinoleoyl species of cardiolipin and an accumulation of monolysocardiolipin within cells. A murine model of Barth syndrome has been developed. Knocked-down cellular models and patient BM cells are characterized by accelerated apoptosis.

Glycogen Storage Disease Type 1b

Glycogen storage disease type 1b is caused by a deficiency in glucose-6-phosphate translocase (transporter) because of mutant *G6PT1 (SLC37A4).* GSD-1b patients experience disturbed glucose homeostasis and quantitative or qualitative neutrophil abnormalities. The translocase transports glucose-6-phosphate into the lumen of the endoplasmic reticulum, where it is hydrolyzed into glucose and inorganic phosphate. Absence of translocase results in an inability to liberate glucose from glucose-6-phosphate. Consequently, patients with GSD-1b are susceptible to fasting hypoglycemia, lactic acidosis, hepatomegaly, poor linear growth, delayed pubertal development, and other systemic complications.

Most patients have neutropenia, which ranges from mild to severe. A strict correlation between genotype and the degree of neutropenia has not been established. Some studies reported hypocellular BM; however, BM testing on nine patients from the City of Hope National Medical Center in 2001 before G-CSF therapy revealed normal to hypercellularity in all patients. Maturation arrest at the myelocyte stage or later is a feature. Neutrophil apoptosis appears to be a central mechanism leading to granulopoietic failure. Neutrophil dysfunction with defective chemotaxis and an impaired respiratory burst is an additional feature. Patients are consequently susceptible to recurrent infections and to inflammatory bowel disease. Infections most commonly involve the skin, perirectal area, ears, and urinary tract, but septicemia, pneumonia, and meningitis may also occur. The most frequently isolated organisms include *Staphylococcus aureus,* group A streptococci, *Streptococcus pneumoniae, Escherichia coli,* and *Pseudomonas*.

G-CSF therapy is extremely effective in almost all GSD-1b patients. BM cellularity increases, the ANCs increase exuberantly, and impaired oxygen radical formation is corrected. AML while on G-CSF is a rare event. Prospective data on GSD-1b patients receiving G-CSF therapy from the SCNIR identified 40% with splenomegaly before starting G-CSF, 81% with splenomegaly by the first year of treatment, and 100% with splenomegaly by 3 years. Hypersplenism can occur but can be overcome by reducing the G-CSF dosage or by splenectomy. Histology of the surgically excised spleens shows extramedullary hematopoiesis.

Kostmann/Severe Congenital Neutropenia: Granulocyte Colony-Stimulating Factor Versus Hematopoietic Stem Cell Transplantation as First-Line Therapy

Therapeutic options for newly diagnosed patients with K/SCN must be constantly reevaluated. It is largely accepted that G-CSF induces robust neutrophilic responses and eliminates infections almost completely in more than 90% of K/SCN patients. Therefore, it should be the first treatment choice. HSCT has been regarded as "salvage" therapy for patients who either acquire evidence of malignant myeloid transformation or fail to respond to G-CSF altogether. For KS patients transplanted with a fully matched donor before transforming to MDS/AML and in stable health, the chance for cure is at least 85%, possibly higher. The SCNIR data support this estimate. Not only is the neutropenia fully corrected by HSCT, but the risk of MDS/AML is also eliminated. The onerous burden of daily subcutaneous injections is removed, the financial expense is relieved, and the side effects of G-CSF are prevented. Clearly, an 85% cure rate stacks up favorably against the high cumulative incidence of incurable MDS/AML over time, particularly in patients who require large doses of G-CSF. HSCT is a reasonable option as front-line therapy for selected higher risk patients instead of G-CSF, and the option should be discussed fairly and sensibly with newly diagnosed patients and families.

Cyclic Neutropenia

Cyclic neutropenia is an autosomal dominant disorder characterized by a regular, repetitive reduction in peripheral blood neutrophils for 3 to 4 days every 19 to 23 days. Between nadirs, the patients have normal or nearly normal neutrophil counts. Patients usually present in infancy or childhood and have a less severe infectious course compared with those with K/SCN. However, life-threatening infections have been reported. Daily treatment with G-CSF typically improves symptoms in most patients.

Cyclic neutropenia is caused by heterozygous mutations in the *ELA2 (ELANE)* gene that normally encodes neutrophil elastase. The mutations usually occur at the active site of neutrophil elastase without disrupting the enzymatic substrate cleavage by the active site. The mutations seem to disturb a predicted transmembrane domain, leading to excessive granular accumulation of elastase and defective membrane localization of the enzyme. The myeloid precursors are characterized by cyclic increases in apoptosis. However, the precise molecular mechanism for the cycling hematopoiesis has not been defined. It is also not clear why the same mutations in *ELA2* are associated with both cyclic and K/SCN phenotypes.

Myelokathexis and WHIM Syndrome

Myelokathexis is a rare autosomal dominant disorder with recurrent bacterial infections caused by a reduced number and function of neutrophils. Neutropenia is typically moderate to severe. Degenerative changes in the granulocytes are characteristic and include pyknotic nuclear lobes, fine chromatin filaments, and hypersegmentation. The BM is usually hypercellular with granulocytic hyperplasia. The pathophysiology of myelokathexis has been attributed to a defective release of BM cells into the peripheral blood. Neutrophil precursors are characterized by decreased expression of BCL-X and accelerated apoptosis. G-CSF ameliorates the neutropenia and leads to clinical improvement during episodes of bacterial infection.

WHIM syndrome refers to the association of myelokathexis with other features (**w**arts, **h**ypogammaglobulinemia, **i**nfections, and **m**yelokathexis). Most cases are caused by mutations in the chemokine receptor gene *CXCR4* but dysfunction of GRK3, a negative regulator of CXCR4, has also been implicated. The mutations result in enhanced chemotactic response of neutrophils in response to the CXCR4 ligand CXCL12 (stroma-derived factor 1) and pathologic retention of neutrophils in the BM. Patients with wild type *CXCR4* might have other genetic defects that lead to an enhanced interaction between CXCR4 and CXCL12 and an enhanced chemotactic response, such as reduced inhibition of CXCL12-promoted internalization, and desensitization of CXCR4 by G protein–coupled receptor (GPCR) kinase-3 caused by decreased transcription of the GPCR kinase-3. G-CSF induces a prompt increase in neutrophil numbers and gamma globulin levels may also increase.

Dursun Syndrome

Dursun syndrome is an autosomal recessive form of SCN caused by biallelic mutant *G6PC3*. Wild-type *G6PC3* encodes glucose-6-phosphatase catalytic subunit 3, which, when mutated, confers an increased susceptibility of neutrophils to apoptosis. BM samples show a marked decrease in mature neutrophils, rendering patients susceptible to severe bacterial infections. Lymphopenia and thrombocytopenia may occur. Structural heart defects, urogenital abnormalities, venous angiectasia on the trunk and extremities, and a broad range of other physical abnormalities are additional features.

Other Inherited Neutropenias

Other inherited neutropenia disorders are associated with specific mutant genes, but they do not necessarily have the K/SCN BM phenotype, nor is their pathophysiology necessarily similar (see Table 27-8). Immune deficiency appears to be an important component of these syndromes. These miscellaneous forms tend to have distinguishing physical abnormalities such as partial albinism and are not predisposed to MDS/AML.

Thrombocytopenia With Absent Radii Syndrome

Background

Thrombocytopenia absent radii syndrome (see Chapters 20) has two essential features, hypomegakaryocytic thrombocytopenia and bilateral radial aplasia with thumbs present. It is one of a group of inherited hematologic disorders that includes FA and DBA with radial ray anomalies. The manifestations of the phenotype vary widely, and patients can present with abnormalities involving skeletal, skin, gastrointestinal, brain, renal, and cardiac systems. The mode of inheritance is not known. Autosomal recessive and autosomal dominant modes with variable penetrance have both been suggested. From published information, families with normal parents have been observed with more than one affected sibling. Additionally, in reports of two sets of identical twins, each child had TAR, but one of a pair of fraternal twins had the syndrome. Almost always, parents of patients with TAR are phenotypically normal. Women with TAR syndrome can conceive and give birth to hematologically and phenotypically normal offspring. The disease is caused by biallelic mutations in *RBM8A*. Three cases of AML and one case of acute lymphoid *(lymphoidic)* leukemia in TAR syndrome patients have been reported. Using a denominator of about 300 published cases of TAR, four leukemic episodes (1%-2% crude rate) suggests a predisposition to the development of hematologic malignancies.

Etiology and Pathophysiology

Thrombocytopenia in TAR syndrome is the result of a defect in megakaryocytopoiesis and thrombocytopoiesis. It was previously shown that TAR patients have submicroscopic deletions at 1q21.1 in one allele in 100% of cases. However, since the deletion was found in about 25% of unaffected parents, the pathogenetic significance of the deletion was unclear. Recently, a group from Cambridge found that TAR syndrome is caused by compound inheritance of a null allele of the RBM8A gene at 1q21.1 and one of two low-frequency SNPs in the regulatory regions of RBM8A, encoding the Y14 subunit of exon-junction complex, which processes mRNA. The mutations caused reduced expression of the protein in platelets from affected individuals.

Thrombopoietin levels in plasma or serum are consistently elevated in TAR syndrome, thereby excluding a cytokine production defect as a cause for thrombocytopenia in this disorder. BM CFU-Meg (CFU-MK) progenitors are either absent or are present in low to normal frequencies but produce small colonies in vitro with abnormal morphology. CFU-GM and BFU-E colony growth is often increased.

In a detailed study of $CD34^+$ cells, the thrombocytopenia of TAR syndrome was associated with a dysmegakaryocytopoiesis characterized by cells remaining at an early stage of differentiation. Cells expressing CD41 without CD42 accumulated behind the block, and there was a decrease in c-mpl transcripts and mpl protein. The response of platelets to adenosine diphosphate or to the thrombin receptor agonist peptide SFLLRN (TRAP) is normal in TAR patients. However, in contrast to control participants, there is no in vitro platelet activation of platelets from TAR patients to recombinant thrombopoietin as measured by testing thrombopoietin synergism to adenosine diphosphate and TRAP in platelet activation. Thrombopoietin-induced tyrosine phosphorylation of platelet proteins in this setting is completely absent or markedly decreased. The results indicate that there is a lack of response to thrombopoietin downstream the c-mpl signal transduction pathway.

No recurrent chromosomal changes are seen in TAR syndrome. Some karyotypic abnormalities found in a few patients are of unclear significance. Clastogenic induced chromosomal breakage analysis in TAR syndrome is normal.

Clinical Features

History and Physical Examination

The diagnosis is made during the newborn period because of the absent radii, and about half of patients develop a petechial rash and overt hemorrhage such as bloody diarrhea. Patients have bilateral radial aplasia (Fig. 27-12) with preservation of the thumbs and fingers on both sides. Additional upper extremity deformities include radial club hands; hypoplastic carpals and phalanges; and hypoplastic ulnae, humeri, and shoulder girdles. Syndactyly and clinodactyly of the toes and fingers are also seen. Characteristic findings include a selective hypoplasia of the middle phalanx of the fifth finger and altered palmar contours. Upper extremity involvement ranges from isolated absent radii to true, often asymmetric, phocomelia. The lower extremities are involved in about half of cases. Malformations include hip dislocation, coxa valga, femoral torsion, tibial torsion, abnormal tibiofibular joints, small feet, and valgus and varus foot deformities. Abnormal toe placement is commonly seen, especially the fifth toe overlapping the fourth. Similar to upper limb involvement, lower extremity deformities range from minimal involvement to complete phocomelia. An asymmetric first rib, a cervical rib, cervical spina bifida, and a fused cervical spine can occur, but trunk involvement is usually minimal. Micrognathia has been associated with the TAR syndrome in up to 65% of cases.

Cardiac abnormalities occur in 15% of the patients, including atrial septal defect, tetralogy of Fallot, and ventricular septal defect. Capillary hemangiomas are common (24%) as well as redundant nuchal folds. Genitourinary tract malformations are detected in 23% of cases. About 95% of patients have short stature, 76% have macrocephaly, and 53% show facial dysmorphism. Structural brain abnormalities may be present. Additional findings are dorsal pedal edema, hyperhidrosis, and gastrointestinal disturbances such as diarrhea and feeding intolerance; almost 50% of patients are intolerant of cow's milk.

Prenatal diagnosis can be made by ultrasound imaging of absent radii with thumbs present and by measuring platelet numbers obtained by fetoscopy or cordocentesis. A published case describes a prenatal diagnosis of TAR followed by an in utero platelet transfusion to facilitate safe delivery.

Figure 27-12 RADIAL APLASIA WITH PRESERVATION OF THE THUMB IN A NEWBORN WITH THROMBOCYTOPENIA WITH ABSENT RADII SYNDROME.

Laboratory Findings

Thrombocytopenia as a result of BM underproduction is a consistent finding. BM specimens show normal to increased cellularity with decreased to absent megakaryocytes. The erythroid and myeloid lineages are normally represented. When a few megakaryocytes can be identified in biopsies, they are small, contain few nuclear segments, and show immature nongranular cytoplasm. If platelet counts increase spontaneously in patients after the first year of life, megakaryocytes increase in parallel and appear more mature morphologically. At diagnosis, leukocytosis is seen in the majority of patients and is sometimes extreme to greater than 100,000/μL with a "left shift" to immature myeloid forms. The cause of this leukemoid reaction is unclear, but it is usually transient and subsides spontaneously. If anemia is present, it is likely attributable to blood loss caused by thrombocytopenia. When platelet numbers are adequate for study, their size is generally normal, and routine testing of function is unremarkable, although some patients may show abnormal platelet aggregation and storage pool defects. Compared with other inherited BM failure syndromes, RBC size and fetal hemoglobin levels are normal.

Differential Diagnosis

Important clinical differences distinguish TAR syndrome from **FA.** In FA, when radii are absent, the thumbs are hypoplastic or absent. FA patients do not have skin hemangiomas like some patients with TAR, but TAR patients do not show abnormal skin pigmentation like 40% of Fanconi patients. Confirmation of FA is made by the clastogenic chromosome stress test showing increased fragility and by mutational analysis. TAR patients do not have increased chromosomal breakage.

Some infants with **trisomy 18** (+18) have absence or hypoplasia of radii and thrombocytopenia. However, in +18, thumbs are absent if radii are absent, and the disorder can also be distinguished from TAR syndrome cytogenetically. There are several syndromes with radial abnormalities but with *normal* platelet counts that can be diagnosed by mutational gene analysis. These include **Roberts syndrome** (mutant *ESC02*); **Holt-Oram syndrome** (mutant *TBX5*); and the clinical spectrum of three disorders caused by mutant *RECQL4:* **Rothmund-Thomson syndrome, Baller-Gerold syndrome,** and **RAPADILINO syndrome.**

Therapy and Prognosis

The risk of hemorrhage is greatest in the first year of life. Deaths are usually caused by intracranial or gastrointestinal bleeding. If patients survive the first year, platelet counts spontaneously increase inexplicably to levels that are hemostatically safe and do not require platelet transfusional support. A minority of patients have sustained, profound thrombocytopenia that does not improve spontaneously. Published cases of TAR syndrome show an actuarial survival curve plateau of 80% by age 1 to 2 years. Many reports of TAR patients antedated the modern use of platelet transfusions so the survival is likely much better currently. TAR patients do not evolve into having BM failure with pancytopenia but may develop acute leukemia in 1% to 2% of cases.

Platelet Transfusions

As in other inherited BM failure disorders associated with thrombocytopenia, platelet transfusions should be used judiciously. Bleeding and prophylaxis for orthopedic surgical procedures are appropriate indications. Persistent platelet counts below 10,000/μL may require preventative platelet transfusions on a regular basis, especially in the first year of life when the expectation is that a spontaneous improvement in platelet number will ensue with time in most infants. Single-donor platelets are preferred to multiple random donor platelets to minimize the risk of alloimmunization. HLA-partially matched or fully matched donors for platelets may be required if patients become refractory to transfusions.

Other Therapies

Supportive management is the mainstay, but in exceptional situations, profound, persistent life-threatening thrombocytopenia can be successfully treated by HSCT. Thrombopoietin receptor agonists, such as romiplostim and eltrombopag, have not been studied in TAR syndrome. Elevated serum thrombopoietin levels at baseline in TAR patients may predict a poor response to these products. IL-11, another thrombopoietic cytokine, has not been studied in clinical trials either; however, endogenous IL-11 serum levels in TAR patients are also elevated. Androgens, corticosteroids, and splenectomy are ineffective therapies for TAR syndrome.

Congenital Dyserythropoietic Anemias

Background

The designation *congenital dyserythropoietic anemia* (CDA) refers to a family of inherited refractory anemias characterized by BM erythroid multinuclearity, ineffective erythropoiesis, and secondary hemosiderosis. The ineffective erythropoiesis is reflected by BM erythroid hyperplasia, inappropriately low reticulocyte counts for the degree of anemia, and intramedullary RBC destruction. Splenomegaly and chronic or intermittent jaundice are additional features. Granulopoiesis and thrombopoiesis are normal. Although these disorders are not classical BM failure syndromes per se, they are genetically transmitted and result in anemia with a blunted erythropoietic response. Some patients, especially with CDA type I, have congenital anomalies.

Three classical forms of CDA have been described as well as a number of variants. An arbitrary classification used in practice for these three is based on the inheritance pattern, the peripheral blood and BM morphology, and the serologic findings in each case. The distinguishing features of the three types of CDA are as follows:

- Type I: Autosomal recessive; macrocytosis; megaloblastic erythroid precursor cells; 2% to 5% binucleated erythroid precursor cells; internuclear chromatin bridges involving polychromatic erythroblasts; negative acidified serum lysis test result (neg Ham test)
- Type II: Autosomal recessive; normocytic RBCs; normoblastic erythroid precursor cells; 10% to 40% binucleated late normoblasts; positive acidified serum lysis test result (pos Ham test)
- Type III: Autosomal dominant (or sporadic); macrocytosis; megaloblastic erythroid maturation; giant multinucleated erythroid precursors with up to 12 nuclei per cell; negative acidified serum lysis test result (neg Ham test)

The designation "type IV" is defunct but was briefly used to classify cases of morphologic CDA type II with a *negative* Ham acidified serum test result. Because some of these were reclassified as CDA type II after retesting using a large panel of heterologous sera, "type IV"

Inherited Marrow Failure and Malignant Leukemic Transformation

Historically, the inherited marrow failure syndromes were classified as "benign" hematology to contrast sharply with hematologic cancer. Patients with KS/congenital neutropenia, SDS, FA, DC, CAMT, DBA, or TAR syndrome often died early in life from complications of cytopenias. However, in the current era of advanced supportive care and availability of recombinant cytokines and other effective therapeutics, patients with these conditions usually survive the early years of life and beyond. With the extended lifespan of patients, the natural history of these disorders has dramatically changed. One of the most sobering observations is that the seven disorders cited above confer an inordinately high predisposition to developing MDS and AML. Thus, the distinction between "benign" and "malignant" hematology in the context of the inherited BM failure disorders has become blurred, and a new clinical and hematologic continuum is evident.

Carcinogenesis occurs as a multistep sequence of events that is driven by genetic damage and by epigenetic factors. In the traditional view, the initiation of cancer starts in a normal cell through mutations from exposure to carcinogens. In the proliferative phase that follows, the genetically altered, initiated cell undergoes selective clonal expansion that enhances the probability of additional genetic damage from endogenous mutations or DNA-damaging agents. Activation of proto-oncogenes, inactivation of tumor-suppressor genes, or inactivation of genomic stability genes may be central in this process. Finally, during malignant conversion and cancer progression, malignant cells show phenotypic changes, gene amplification, chromosomal alterations, and altered gene expression.

With respect to the seven inherited BM failure syndromes that are predisposed to develop hematologic cancers, there is reason to believe that leukemogenesis is also a multistep process. The first genetic "hit" or leukemia-initiating step may be the syndrome-specific inherited genetic abnormality itself, which initially manifests as the single- or multiple-lineage marrow failure state. The "predisposed" progenitor, already initiated, could conceptually develop decreased responsiveness to the signals that regulate homeostatic growth, terminal cell differentiation, or programmed cell death. Leukemic promotion and progression with clonal expansion leading to MDS or AML could then ensue readily. Because many of the mutant genes that produce the inherited BM failure syndromes have been discovered, the nature of the leukemogenic-initiating events in these conditions should become evident.

Three of the syndromes illustrate the point. The best example is the multistep evolution of leukemic transformation over time in patients with congenital neutropenia while taking G-CSF. The acquisition of activating RAS oncogene mutations, cytogenetic abnormalities involving primarily +7, 7q- and +21, and G-CSF receptor mutation occurs in the majority of patients who transform.

Other than clonal cytogenetic changes, we know little about the timeline or sequence of events that characterize the malignant phenotype of SDS. It is striking, though, that the syndrome from early age already shares many of the findings of de novo adult MDS, including abnormal hematopoietic colony growth, abnormally short leukocyte telomeres, elevated apoptotic index mediated by FAS/FAS ligand, an abnormal immune system, an aberrant marrow microenvironment that shows impaired support of normal hematopoiesis, and increased microvessel density. Many, if not all, of these findings may evolve in utero.

Finally, FA has a "short cut" mechanism to leukemic conversion. Biallelic mutant genes from conception result in genomic instability, compromised DNA repair and chromosome breakage. The opportunities for blood cancers in this setting are infinite. Actuarial data from the IFAR showed that the risk of acquiring clonal cytogenetic abnormalities was 67% by 30 years of age in patients with BM failure. The actuarial risk of MDS or AML was 52% by 40 years of age. This steady tempo of leukemic evolution implies a stepwise acquisition over time of additional, critical genetic "hits" before overt MDS/AML.

is no longer used as a category. There are also several other forms of CDA that are distinct from CDA types I, II, and III. Some of these variants have been identified in three or more families and have been tentatively classified phenotypically into CDA *groups* (not types) IV, V, VI, and VII (see section below, Other CDAs). Additional CDA's are associated with specific gene mutations other than those seen in CDA I and II. The growing number of variants underscores the complex nature of CDA and the current direction to reclassify these disorders accurately by genotype rather than by morphology.

Etiology, Genetics, Pathophysiology, and Clinical Features

CDA Type I

Congenital dyserythropoietic anemia I is inherited in an autosomal recessive manner. The disorder is caused by biallelic mutant *CDAN1*. The gene was identified in highly inbred Israeli Bedouins. The gene product, codanin-1, may be involved in nuclear envelope integrity, but this is uncertain, and little is known about pathogenesis.

In several reported families, more than one sibling was affected, and the disorder has been seen in fraternal and identical twins. The onset of anemia, jaundice, and other symptoms may be noted at any age, especially in neonates. Eighty percent of infants in a recent large series required blood transfusions during the first month of life. One case was reported with anemia in utero requiring intrauterine exchange transfusions at 28 and 30 weeks' gestation. Affected patients often have some degree of icterus and splenomegaly.

Congenital dyserythropoietic anemia I can be associated with a variety of congenital anomalies. The following have been catalogued: patches of brown skin pigmentation, syndactyly in the feet, absence of phalanges and nails in the fingers and toes, an additional phalanx, duplication or hypoplasia of metatarsals, short stature, pigeon chest deformity, varus deformity of hips, flattened vertebral bodies, a hypoplastic rib, congenital ptosis, Madelung deformity of the wrist, and deafness. The pigmentation, syndactyly and absence of phalanges and nails are not common in CDA I patients but appear to be quite specific for this subtype. Dysmorphic features are seen in up to 65% of patients. Three siblings from a Bedouin family presented with neonatal pulmonary hypertension. In a French family, three siblings had sensorineural deafness and a lack of motile sperm cells.

Laboratory Abnormalities. The degree of anemia is usually mild to moderate (hemoglobin in the range of 6.6-11.6 g/dL), and RBCs appear macrocytic. Peripheral blood RBC morphology is characterized by anisocytosis and poikilocytosis, and occasionally Cabot rings are seen. Cabot rings appear to be unique to CDA I and are not seen in types II and III. White blood cells and platelets are normal. Examination of the BM reveals erythroid hyperplasia with some megaloblastic erythropoiesis and a small number of erythroblasts with dyserythropoietic features. The unique morphologic abnormality seen in CDA I is the presence of chromatin bridges between nuclei of two separate erythroblasts, a reflection of impaired cellular division (Fig. 27-13). This internuclear bridging of erythroblasts seen with light microscopy is also a common feature in MDS. Electron microscopy reveals additional abnormalities that include widening of the nuclear membrane pore space with cytoplasmic invagination into the nucleus, separation of nuclear chromatin, and chromatin condensation, all of which give the general appearance of a spongy nucleus (Fig. 27-14). Dyserythropoiesis seems limited mostly to more mature RBC precursors. In contrast to CDA II, there are no unique serologic features.

The defect in CDA I is at the stem cell level. The numbers of CFU-E and BFU-E colonies are normal but contain a mixture of normal and abnormal cells when examined by electron microscopy. This suggests that the abnormality is expressed variably in the mature progeny of each stem cell. Erythroid precursors also demonstrate S phase arrest and morphologic features of apoptosis. In some CDA I patients, hemoglobin A_2 levels are increased. Also, some cases show unbalanced globin chain synthesis. Patients do not have thalassemia, and the cause of these findings is not known.

CDA Type II (HEMPAS)

Congenital dyserythropoietic anemia II is commonly known as HEMPAS, an acronym for hereditary erythroblastic multinuclearity with a positive acidified serum test. It is inherited in an autosomal recessive manner. The disorder is caused by biallelic mutant *SEC23B*. The wild-type gene encodes the SEC23B component of the coat protein (COP) II complex. COP II vesicles transport secretory proteins from the endoplasmic reticulum to the Golgi complex. Mutations result in misglycosylation and an impaired clearance of endoplasmic reticulum cisternae past a given point during erythroid differentiation.

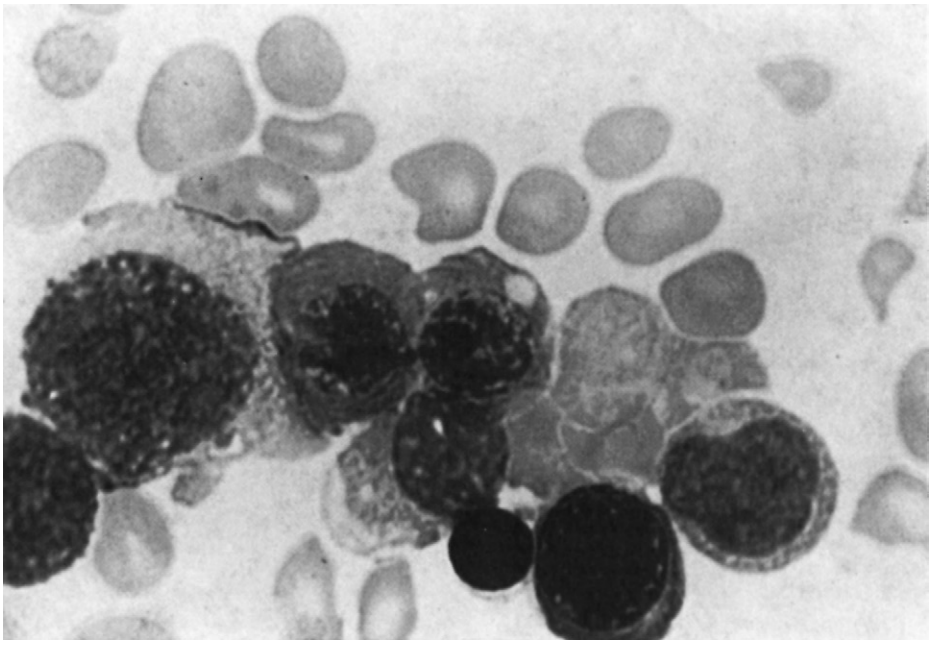

Figure 27-13 BONE MARROW FROM PATIENT WITH CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE I. Erythroblasts are connected by internuclear bridges between two cells. *(Provided by Dr. Jean Shafer, Rochester, NY.)*

Compared with the other CDAs, the pathogenesis of CDA II has been almost completely clarified. At the stem cell level, in vitro culture of CDA II erythroid progenitors produces CFU-E and BFU-E colonies with erythroblast multinuclearity. Initially, studies of peripheral blood CDA II RBCs identified a number of chemical abnormalities, including unbalanced globin chain synthesis, increased membrane glycolipids, and altered RBC membrane protein patterns demonstrated by two-dimensional electrophoresis. Furthermore, glycoproteins on CDA II RBCs were found to have an abnormal carbohydrate structure, leading to aberrant reactivity with anti-i sera. Additional data suggested that the IgM antibody responsible for hemolysis in the acidified-serum lysis test (Ham test) recognized an abnormal glycolipid structure sharing homology with i and I antigens. Thus, a variety of data predicted and confirmed that abnormalities in the glycosylation pathway were involved in the etiology of CDA II.

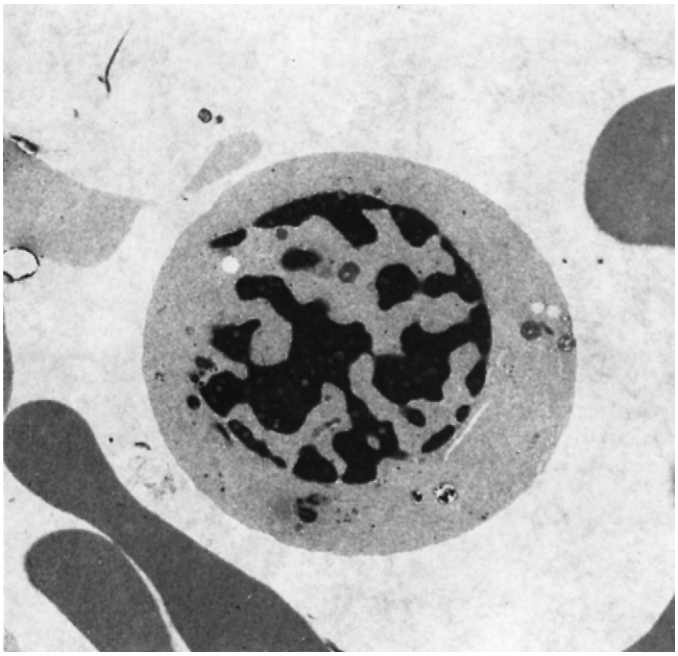

Figure 27-14 ELECTRON MICROSCOPY OF BONE MARROW FROM CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE I. Note the "spongy" appearance of the nucleus resulting from uneven chromatin with cytoplasmic invagination into the nucleus. *(Provided by Dr. Raoul Fresco, Maywood, Ill.)*

The two major defects in the CDA II glycosylation enzymatic pathway are a deficiency of α-mannosidase II and of *N*-acetylglucosaminyl transferase II. A third defect in a CDA II variant is deficient levels of the membrane-bound form of galactosyl transferase. All three of these enzymatic deficiencies lead to abnormal oligosaccharides on major erythrocyte proteins such as the anion transporter Band 3 that could cause disruption of the structural network of erythrocytes and their precursors, thereby leading to their premature demise. Defective glycosylation on the RBC surface may also affect the regulation of complement on the surface of erythrocytes. Enhanced functional activity of the alternative pathway C3 convertase and of the membrane attack complex may result from the improper glycosylation of glycophorin A, which has been proposed to serve as a complement regulatory protein. These abnormalities are not a consequence of quantitative or functional deficiencies of the complement regulatory proteins CD55 or CD59.

Laboratory Abnormalities. There is overlap of some clinical and laboratory manifestations between CDA I and CDA II, but there are three major differences. The first is that the magnitude of anemia is usually more severe, and patients, especially children, often require RBC transfusions. Peripheral blood RBCs are usually normocytic but show anisocytosis and poikilocytosis (Fig. 27-15). The second difference is that the BM in CDA II reveals greater numbers of abnormal erythroblasts with binuclearity in up to 35% late erythroblasts, as well as multinuclearity and abnormal lobulation (Fig. 27-16). These nuclear abnormalities are seen only in the late erythroblasts, not in basophilic erythroblasts. Karyorrhexis is commonly observed, and pseudo-Gaucher cells may be present, representing the ingestion of debris by histiocytic cells from ineffective erythropoiesis. Electron microscopy of late erythroblasts also reveals an excess of endoplasmic reticulum parallel to the cell membrane, giving the appearance of a double cell membrane (Fig. 27-17). A third difference, which is also a pathognomonic finding, is that CDA II RBCs are lysed by acidified (pH, 6.8) sera obtained from approximately 30% to 60% of fresh ABO-compatible sera from normal persons (i.e., a positive Ham test result), but there is no lysis when RBCs are incubated with the patient's own acidified serum. This lysis is a result of a naturally occurring IgM antibody that recognizes an antigen on CDA II cells and binds complement; this antibody can be removed by

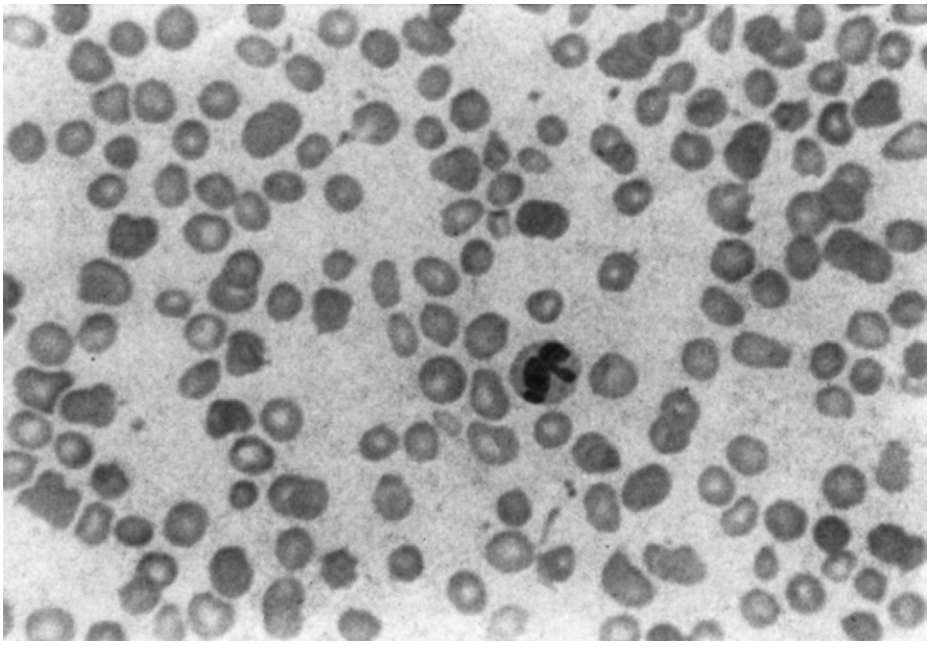

Figure 27-15 PERIPHERAL BLOOD SMEAR FROM A PATIENT WITH CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE II. Note the marked variation in red blood cell size and shape.

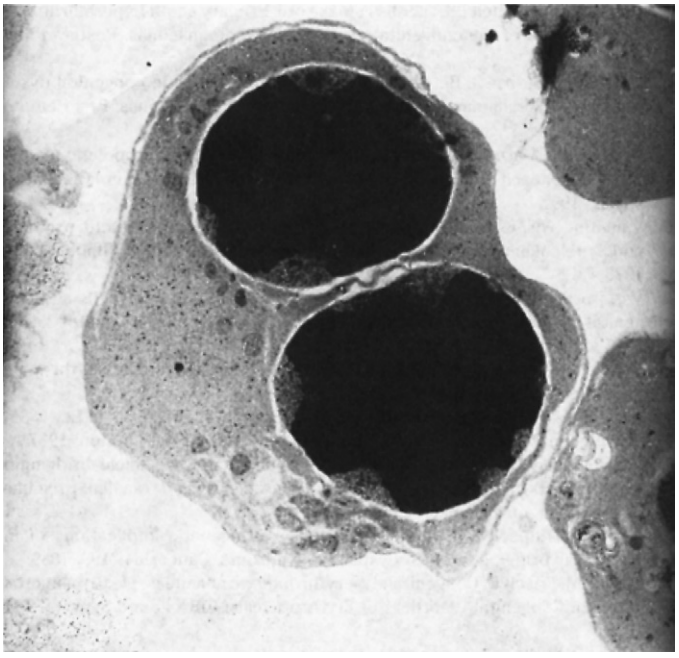

Figure 27-17 ELECTRON MICROSCOPY OF A BONE MARROW ERYTHROBLAST FROM A PATIENT WITH HEMPAS (CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE II). Note the appearance of a double cell membrane, reflecting an excess of endoplasmic reticulum. *(Provided by Dr. Raoul Fresco, Maywood, Ill.)*

preincubating normal sera with HEMPAS erythrocytes. However, the specific HEMPAS antigen recognized by this antibody is not known. In contrast to HEMPAS, the erythrocytes of patients with paroxysmal nocturnal hemoglobinuria (PNH) undergo lysis when the acidified serum is from the PNH patient or from normal donors. Another difference is that PNH erythrocytes undergo lysis in isotonic sucrose (sugar water test), but HEMPAS RBCs do not lyse in isotonic sucrose.

The erythrocytes from patients with CDA II also exhibit an increased agglutinability and lysis to anti-i and anti-I sera and manifest increased expression of both antigens. These surface antigens are complex carbohydrate structures found predominantly on fetal and adult RBCs, respectively. Increased expression of i antigen can be demonstrated on all RBCs in CDA II using fluorescent labels. Relatives of patients with CDA II who have normal BM but increased agglutinability to anti-i appear to be heterozygote carriers of this disorder. HEMPAS erythrocytes bind a normal amount of complement (C1), but more antibody and less C4 than normal. This causes binding of an excess of C3 and hemolysis.

The number of erythroid progenitors is probably normal in BM and blood. Although one study found only normal morphology of the erythroblasts produced in culture, subsequent studies reported multinuclearity similar to that seen in the BM. As in CDA I, the defect in CDA II is in the erythroid progenitor cell and is expressed variably in more mature erythroblasts.

Patients with CDA II may develop progressive, lifelong iron overload even in the absence of transfusions, and approximately 20% develop cirrhosis as a consequence. Splenomegaly occurs in the majority of patients with CDA II. A number of other clinical associations with CDA II have been reported such as mental retardation, Sweet syndrome, von Willebrand disease, and Dubin-Johnson syndrome, among others. Rather than true associations, it is likely that the majority represent coincidental occurrences. An adult patient was reported with an extramedullary hematopoietic mass in the posterior mediastinum that was a result of BM expansion associated with ineffective erythropoiesis. In a retrospective study of 41 patients, coinheritance of Gilbert syndrome was associated with a significantly increased risk of hyperbilirubinemia and early-onset gallstone formation.

CDA Type III

Based on reported CDA cases, type II is the most common CDA, type I is next, and CDA III is the rarest of the three major forms. In contrast to the other two forms, CDA III is inherited as an autosomal dominant disorder. The responsible gene maps to chromosome 15q21-q25, but little is known about CDA III pathophysiology. Sporadic cases have also been described. These latter cases with hematologically normal parents and relatives may represent autosomal recessive inheritance or may have been caused by spontaneous dominant mutations. In a Swedish family with 31 cases inherited in an autosomal dominant mode, an excess number of cases with a monoclonal gammopathy and myeloma have occurred. Also, an adult patient with CDA III was described with T-cell non-Hodgkin

lymphoma. These cases, plus a case of Hodgkin disease occurring in an additional patient, may indicate an increased incidence of lymphoproliferative diseases in CDA III.

Laboratory Abnormalities. In CDA III, splenomegaly is usually minimal or absent. The anemia is usually mild to moderate, but transfusion-dependent patients have been observed. The circulating RBCs can be normal or mildly macrocytic. BM examination shows erythroid hyperplasia. Giant erythroblasts with up to 12 nuclei are the most distinctive feature of CDA III observed on light microscopic examination of the BM. These may appear similar to some of the large multinucleated cells seen in CDA II (see Fig. 27-16). Abnormally large lobulated nuclei and discordance in nuclear maturation are also found. Although they are hallmarks of CDA III, these findings are not pathognomonic and may be seen in erythroleukemia. Electron microscopy demonstrates nuclear clefts and blebs, autolytic areas within the cytoplasm, and iron-filled mitochondria. In some dominantly inherited and sporadic cases of CDA III, electron microscopy reveals that an occasional erythroblast section contains stellate or branching electron-dense intracytoplasmic inclusions. These are morphologically indistinguishable from those in HbH disease and consist of precipitated β-globin chains.

The acidified-serum lysis test result is negative in CDA III. Agglutination and lysis of erythrocytes to anti-i antibody has only been examined in a few cases of CDA III with conflicting findings. Serum thymidine kinase was measured in 20 CDA III patients and 10 healthy siblings. Elevated thymidine kinase was found in all 20 cases but was normal in the siblings. It is suggested that measuring thymidine kinase levels can allow clinicians to discriminate between affected individuals and healthy siblings without performing a BM aspirate.

Other CDAs: Classifiable and Nonclassifiable Variants

Dozens of cases of CDA have been reported that do not conform to the classification of types I, II, and III. Some of the earlier reports of variants may or may not have been CDAs. In an attempt to sort out some of the better-documented cases, a phenotype-based classification was proposed that assigns patients to one of four groups (not types), designated groups IV, V, VI, and VII. To qualify for inclusion in this classification, each group contains cases from three or more unrelated families. The features of each are as follows.

CDA Group IV. This group has severe anemia, transfusion dependence from birth, marked erythroid hyperplasia, normoblastic or mild to moderate megaloblastic changes, up to 8% BM erythroblasts with markedly irregular or karyorrhectic nuclei, and an absence of precipitated protein within erythroblasts by electron microscopy. An infant with group IV CDA presented with hydrops fetalis. The spleen is enlarged. The inheritance is not clear.

CDA Group V. Patients have normal or near-normal hemoglobin levels, a normal or slightly elevated MCV, and an increased serum unconjugated bilirubin. The BM shows marked erythroid hyperplasia and normoblastic or mild to moderate megaloblastic changes. The spleen may be palpable. The condition has been previously described as "primary shunt hyperbilirubinemia." Inheritance is variable and appears to be autosomal recessive in some cases but possibly autosomal dominant or X-linked in others. In CDA group V, the BM macrophages engulf morphologically normal but functionally abnormal erythroblasts.

CDA Group VI. This group is characterized by marked macrocytosis (MCV 119-125 fL) with little or no anemia and grossly megaloblastic erythropoiesis. There may be mild jaundice and an increased serum bilirubin. The differential diagnosis includes orotic aciduria and thiamine-responsive anemia. Vitamin B_{12} and RBC folate levels are normal.

CDA Group VII. These patients have severe transfusion-dependent anemia from birth, marked erythroid hyperplasia, normoblastic or nonspecific dysplastic changes, markedly abnormal nuclear shapes in many erythroblasts, and intraerythroblastic inclusions resembling precipitated α globin chains. The inclusions do not react with monoclonal antibodies against α and β globin chains. The diagnosis requires the exclusion of β-thalassemia trait in the parents.

Unclassifiable cases of CDA have been reported with lifelong anemia that was probably inherited. These cases were characterized by marked aniso- and poikilocytosis and occasional teardrop and fragmented erythrocytes in the peripheral blood. Hyperplastic BM showed megaloblastoid features without multinuclearity or ringed sideroblasts, but a case with prominent ringed sideroblasts was also described. Unlike classical CDA, neutropenia or thrombocytopenia has been observed in some of these patients. Cytogenetic studies of BM revealed no clonal chromosomal abnormalities. Reticulocyte response to anemia was absent or inappropriately low in all. Most studies of parents failed to reveal abnormalities, suggesting an autosomal recessive mode of transmission.

Variant CDAs Associated With Specific Gene Mutations

GATA1 is a transcription factor closely linked with erythropoiesis and megakaryopoiesis. The Val205Met mutation in the ***GATA1*** gene underlies a CDA with dyserythropoiesis and thrombocytopenia**.** The ***KLF1*** gene encodes an erythroid transcription factor. A specific mutation of *KLF1* produced a severe form of CDA with basophilic stippling of polychromatic erythroblasts and erythrocytes, marked abnormalities of nuclear shape, and increased expression of embryonic and fetal hemoglobin. A case of hereditary cryostomatocytosis and dyserythropoiesis was caused by a de novo erythroid anion exchanger **band 3 mutation.** The BM morphology showed dyserythropoiesis characteristic of CDA I and CDA II. Mutant ***MVK*** resulted in mevalonate kinase deficiency, dyserythropoietic anemia, and BM findings similar to those in CDA II. A syndrome of dyserythropoietic anemia, exocrine pancreatic insufficiency, and calvarial hyperostosis was caused by a mutation in ***COX412,*** a gene highly expressed in BM.

Differential Diagnosis

Marrow erythroblast multinuclearity is seen with other hematologic disorders, but these can be readily distinguished from CDA. The **megaloblastic anemias** have a different clinical presentation and are identified in the laboratory by the presence of hypersegmented neutrophils, decreased RBC folate values, or reduced serum levels of vitamin B_{12}. The **MDS** may manifest as an isolated refractory anemia, but they often present with bi- or trilineage cytopenias that contrast sharply with CDA. The MDS subsets may also show BM granulocytic and megakaryocytic morphologic abnormalities, the presence of myeloblasts, ringed sideroblasts, and clonal cytogenetic changes. **Erythroleukemia** (AML, M6) is another cause of marked dyserythropoiesis, but typically there is pancytopenia, the erythroblasts are avidly positive for the periodic acid-Schiff stain, and the BM cells may show a clonal cytogenetic marker. The **β-thalassemia syndromes** differ from CDA by the presence of marked microcytosis with elevated levels of hemoglobin A_2, fetal hemoglobin, or both.

Therapy and Prognosis

In general, the CDAs are associated with a favorable long-term prognosis. For example, CDA I can be diagnosed late in life. One reported case was associated with a relatively benign course over a 30-year follow-up. Clinical manifestations of the CDAs may include intermittent jaundice and dark urine caused by increased hemoglobin catabolism or signs and symptoms of anemia. Rarely, hyperbilirubinemia without anemia may be the initial presentation of CDA patients. Cholelithiasis may be present as a consequence of chronic hyperbilirubinemia.

Anemia is typically mild in most cases of CDA and requires no intervention, but in more severe presentations, especially those requiring transfusional support, splenectomy may be beneficial. Most of the experience showing an improvement in hemoglobin levels after splenectomy has been in CDA II; the benefit of splenectomy in CDA I is less clear. Splenectomy may cause a persistent thrombocytosis in CDA types I and II and contribute to the development of Budd-Chiari syndrome and portal vein thrombosis.

Treatment of all forms of CDA with androgens, corticosteroids, vitamin E, vitamin B_{12}, folic acid, pyridoxine, or iron is ineffective in ameliorating the anemia. Iron therapy is also contraindicated because of the underlying propensity for hemosiderosis secondary to ineffective erythropoiesis, transfusional iron overload, increased gut iron absorption, and downregulation of the primary regulator of iron absorption, hepcidin. Even if regular RBC transfusions are not initiated, patients should be routinely monitored for evidence of iron overload. Iron chelation with daily subcutaneous infusions of deferoxamine (Desferal) has been underused in CDA even though deaths have been recorded from hemochromatosis. The value of the oral iron chelator deferasirox (Exjade) has not been defined yet for the CDAs.

Phlebotomy has been carried out to remove iron in selected CDA patients, but this could result in a worsening of the anemia and theoretically enhance gut iron absorption. An additional concern is that CDA patients seem predisposed to hepatic cirrhosis irrespective of body iron burden. The pathogenesis of this is unclear.

Interferon-α-2a or INF-α-2b therapy given two or three times a week or peg-INF-α-2a once a week, increase hemoglobin levels and decrease iron overload in most CDA I patients who require repeated transfusions for moderately severe anemia. Erythrokinetic studies demonstrate a striking reduction of ineffective erythropoiesis in patients receiving INF, and electron microscopy shows a reduction in nuclear structural abnormalities. INF therapy should also be considered in moderately anemic CDA I patients before treatment of iron overload with phlebotomy. Patients with CDA II do not respond to INF-α.

Hematopoietic stem cell transplantation has been curative in a few severe cases of CDA, including transfusion-dependent CDA type I, CDA type II, Ham test–negative "CDA type II," and an unclassifiable CDA.

Asymptomatic extramedullary hematopoiesis may mimic tumors of the mediastinum, abdomen, and vertebral column. Because of the increased RBC production that occurs, the development of sites of extramedullary hematopoiesis may result in an amelioration of the degree of anemia. Technetium-99m sulfur colloid scintigraphy is useful in delineating the extent of these regions.

Future Directions

Identification of the various mutant genes for the CDA types will facilitate a more precise classification than the phenotype-based system used currently. The wild-type protein product of *CDAN1* requires further research to clarify its function in health and its role in producing CDA type I when mutated. Strategies are required for managing iron overload similar to those for Diamond-Blackfan anemia and thalassemia major. In this regard, the therapeutic benefit of oral iron chelators such as Exjade should be explored fully.

CHAPTER 28

APLASTIC ANEMIA

Neal S. Young and Jaroslaw P. Maciejewski

Aplastic anemia (AA), the paradigm of the bone marrow (BM) failure syndromes, is most simply defined as peripheral blood pancytopenia and a hypocellular BM (Fig. 28-1). From epidemiologic and clinical features, pathophysiologic studies, and response to therapy, AA is a distinctive disease. However, the diagnosis of AA requires excluding other causes of pancytopenia (Table 28-1). AA can occur as a primary hematologic disorder, most often idiopathic, or apparently result from various proximate causes, including obvious physical and chemical toxins but also drugs and viruses that can act indirectly. Although AA is usually characterized by a severe diminution in BM function that affects all the hematopoietic lineages, granulocyte, platelet, and red blood cell (RBC) levels may not be depressed uniformly, and less severe degrees of BM hypoplasia and odd combinations of bicytopenias and monocytopenias can occur. AA can be especially difficult to distinguish from hypocellular myelodysplasia, a diagnostic dilemma that can rest on real biologic similarities. Even typical AA can vary in its clinical presentation and course, from a fulminant illness marked by continuous or recurrent hemorrhage and major infections to an indolent process manageable by transfusion therapy alone. Readers are referred to previous editions of this textbook for references, as well as to the authors' recent reviews.[1,2]

HISTORY

The study of BM failure dates to 1888, when Paul Ehrlich described a young woman who died after an explosive short illness marked by severe anemia, bleeding, and high fever. As a pathologist, Ehrlich was struck by the absence of nucleated RBCs and the fatty quality of the femoral BM. Vaquez and Aubertin, in a 1904 case report of "pernicious anemia with yellow marrow," named the disease and emphasized a pathophysiology of "anhematopoiesis." The etymologic root of the term *aplastique* is the Greek verb *pl¿Jw,* to create and give shape to (*¿plaztká,* the adjective, unformed). Early inferences about the cause of the disease were made from the BM appearance at autopsy. Pathologically, the watery, yellow BM seen uniquely characterized the aplasia, but the limited and rather general clinical signs were less helpful in distinguishing this type of a regenerative BM failure from other anemias.

CLASSIFICATION

AA is a major sequela of irradiation and exposure to cytotoxic chemotherapy. It has been associated with the use of chemicals and drugs, viral infections, and other diseases (Table 28-2). Most patients have an idiopathic form of the disease. Too strict a division of cases into categories can obscure important pathophysiologic relationships. Historical associations of environmental exposures and causation are interesting but should be considered with some skepticism because of biases of observation and reporting and lack of direct evidence in most cases.

EPIDEMIOLOGY

Incidence and Geographic and Age Distribution

The largest and most comprehensive study of the epidemiology of BM failure was the International Aplastic Anemia and Agranulocytosis Study (IAAAS) conducted in Europe and Israel from 1980 to 1984.[3] IAAAS was performed prospectively and applied strict case definition to pathologically confirmed cases. Using stringent criteria, the overall annual incidence of AA was two cases per 1 million people. The incidence rates reported in the IAAAS are three- to fourfold lower than rates reported in many earlier, mainly retrospective, and far less well-designed surveys.

A remarkable feature of the epidemiology of AA is the unexplained geographic variation in its incidence. The incidence of AA in Bangkok and two rural regions of Thailand has been accurately determined using the same methods as those used by the IAAAS researchers in Europe and Israel; the annual incidence was 4.0 cases per 1 million people in the capital and 5.6 cases per 1 million people in the northeastern province of Khonkaen.[4] The incidence in China has been estimated to be 7.4 cases per 1 million people annually. From published, hospital-based series, personal communications, and firsthand observations, AA appears more prevalent in less developed regions of the world. There are no major sex or racial differences in the occurrence of AA.[3]

Aplastic anemia is a disease of the young (Fig. 28-2). Most patients present between 15 and 25 years of age or older than 60 years of age.

Epidemiologic Clues to Causality

Population-based studies have investigated possible causal associations. Drugs are implicated in only approximately 25% of cases of AA in the West; in Thailand, AA was attributed to drug exposure in only approximately 15% of cases.[4] There are associations with chemical exposures, exposures to viruses, hepatitis, and occupation. There is evidence that geographic variation in AA might result from environmental causes[4] and a genetic predisposition.

Genetic Aspects

In children and young adults, acquired AA should be distinguished from the main inherited forms of BM failure, Fanconi anemia (FA) and dyskeratosis congenita (DKC). Identification of constitutional AA has important therapeutic implications. Patients with FA and DKC can lack typical physical anomalies, and the pancytopenia can develop long after childhood (see Chapter 27), mimicking acquired disease. The distinction between inherited and acquired AA has been blurred with the identification of mutations in the telomerase genes that appear to be risk factors rather than determinants of clinical BM

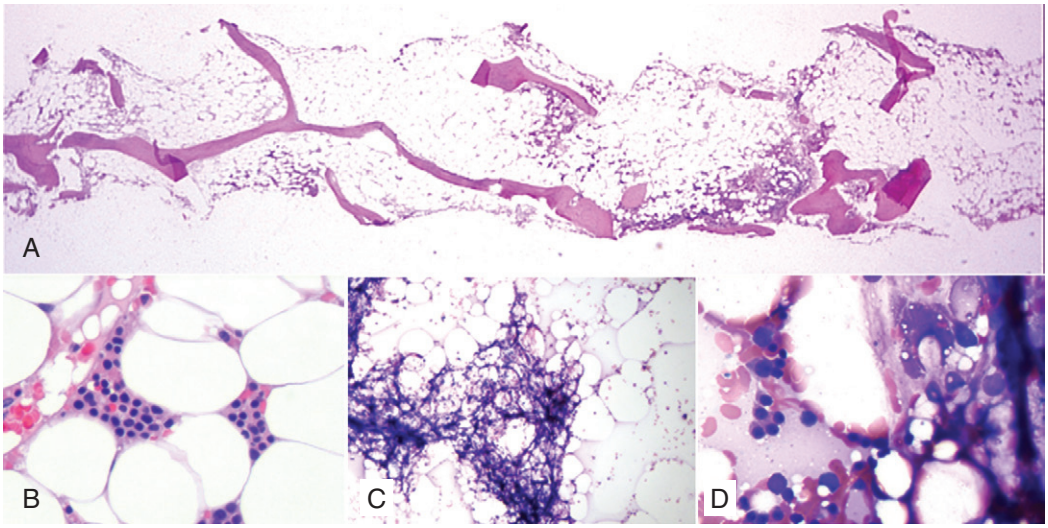

Figure 28-1 BONE MARROW MORPHOLOGY IN SEVERE APLASTIC ANEMIA. Bone marrow biopsy specimen of sufficient length **(A)** shows severe hypocellularity with a few "hot spots" of hematopoietic activity. These are sometimes predominantly erythroid **(B).** The corresponding aspirate (**C** and **D**) shows empty marrow spicules and residual stoma, including lymphoid cells, plasma cells, histiocytes, mast cells, and a few hematopoietic elements.

Table 28-1 Differential Diagnosis of Pancytopenia

Pancytopenia With Hypocellular Bone Marrow
Acquired aplastic anemia
Inherited aplastic anemia (Fanconi anemia and others)
Some myelodysplasia syndromes
Rare aleukemic leukemia (acute myeloid leukemia)
Some acute lymphoblastic leukemias
Rare lymphomas of bone marrow
Pancytopenia With Cellular Bone Marrow
Primary bone marrow diseases
Myelodysplasia syndromes
Paroxysmal nocturnal hemoglobinuria
Myelofibrosis
Some aleukemic leukemias
Myelophthisis
Bone marrow lymphoma
Hairy cell leukemia
Secondary to systemic diseases
Systemic lupus erythematosus, Sjögren syndrome
Hypersplenism
Vitamin B_{12}, folate deficiency (familial defect)
Overwhelming infection
Alcohol
Brucellosis
Ehrlichiosis
Sarcoidosis
Tuberculosis and atypical mycobacteria
Hypocellular Bone Marrow ± Cytopenia
Q fever
Legionnaires disease
Mycobacteria
Tuberculosis*
Anorexia nervosa, starvation
Hypothyroidism

*Pancytopenia in tuberculosis only rarely is associated with a hypocellular bone marrow at biopsy or autopsy. Marrow failure in the setting of tuberculosis is almost always fatal; exceptional patients probably had underlying myelodysplasia or acute leukemia.

Table 28-2 A Classification of Aplastic Anemia

Acquired Aplastic Anemia
Secondary aplastic anemia
Irradiation
Drugs and chemicals
Regular effects
Cytotoxic agents
Benzene
Idiosyncratic reactions
Chloramphenicol
Nonsteroidal antiinflammatory drugs
Antiepileptics
Gold
Other drugs and chemicals
Viruses
Epstein-Barr virus (infectious mononucleosis)
Hepatitis virus (non-A, non-B, non-C, non-G hepatitis)
Parvovirus (transient aplastic crisis, some pure red blood cell aplasia)
Human immunodeficiency virus (acquired immunodeficiency syndrome)
Immune diseases
Eosinophilic fasciitis
Hyperimmunoglobulinemia
Thymoma and thymic carcinoma
Graft-versus-host disease in immunodeficiency
Paroxysmal nocturnal hemoglobinuria
Pregnancy
Idiopathic aplastic anemia
Inherited Aplastic Anemia
Fanconi anemia
Dyskeratosis congenita
Shwachman-Diamond syndrome
Reticular dysgenesis
Amegakaryocytic thrombocytopenia
Familial aplastic anemias
Preleukemia (e.g., monosomy 7)
Nonhematologic syndromes (e.g., Down, Dubowitz, Seckel)

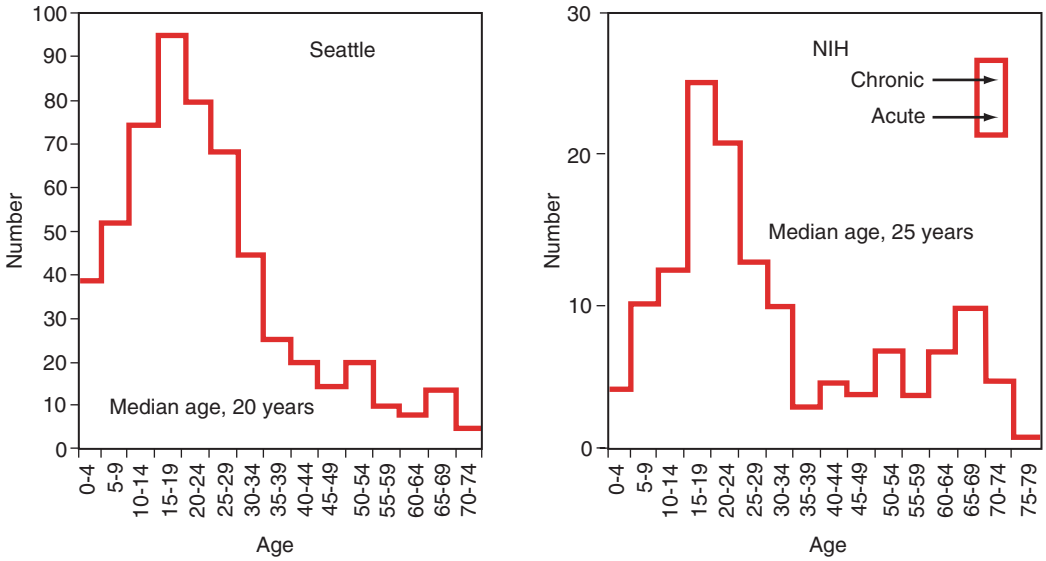

Figure 28-2 DISTRIBUTION OF APLASTIC ANEMIA BY AGE. For the patients at the University of Washington, a major transplantation center, the age given is at the time of first treatment. For the patients at the National Institutes of Health (NIH), where immunosuppressive therapy is offered, the age given is at the time of diagnostic bone marrow biopsy. Acute disease is defined as less than 3 months between diagnosis and presentation at NIH, and chronic disease is defined as more than 3 months. *(Seattle statistics courtesy Rainer Storb, University of Washington.)*

failure (see later discussion). Genomic approaches to the study of AA are likely to uncover other genetic contributions to susceptibility to BM failure.[5,6]

A few histocompatibility types have also been associated with AA, most consistently human leukocyte antigen (HLA)-DR2. HLA-DR subtypes have proved useful in predicting response to immunosuppressive therapy; in a large cohort of U.S. AA patients, HLA-DR15 was associated with the presence of the paroxysmal nocturnal hemoglobinuria (PNH) clone and responsiveness to immunosuppression. Genetic predisposition may be responsible for some idiosyncratic reactions to drugs and chemicals leading to the development of AA. Polymorphisms in cytokine genes, associated with an increased immune response, also are more prevalent in AA; examples include a nucleotide polymorphism in the tumor necrosis factor-α (TNF-α; *TNF2*) promoter at −308, homozygosity for a variable number of dinucleotide repeats in the gene encoding γ-interferon (IFN-γ), and polymorphisms in the interleukin 6 (IL-6) gene. Genome-wide transcriptional analysis of T and natural killer cells from AA patients has implicated pathologic expression of components of innate immunity, including Toll-like receptors.

ETIOLOGY AND PATHOGENESIS

Hematopoiesis in Bone Marrow Failure

Stem Cells

A consistent laboratory finding for patients with AA is a very low number of hematopoietic progenitor cells. Deficient colony formation by BM cells of AA patients remains unresponsive even to high levels of hematopoietic growth factors. The total number of progenitors in a BM sample is reduced, and the number of colony progenitor cells assayed from a purified CD34 population is low. Long-term culture-initiating cells (LTC-ICs), a stem cell surrogate assay, also are profoundly deficient in all patients with severe AA. At clinical presentation, the number of LTC-ICs is usually less than 10% of normal; combined with a reduction in total BM cellularity to 10% or less, the stem cell number is estimated to be reduced to 1% or less than normal in patients with AA (Fig. 28-3).

Telomeres and Bone Marrow Failure

One peculiar feature of white blood cells (WBCs) in AA is short telomeres. The discovery, first by linkage analysis in large pedigrees, that the X-linked form of DKC was caused by mutations in *DKC1* and subsequently purposeful identification of mutations in *TERC* in some autosomal dominant patients with this constitutional BM failure syndrome implicated a genetic basis for telomere deficiency. Central to the repair machinery is an RNA template, encoded by *TERC,* on which telomerase, a reverse transcriptase encoded by *TERT,* elongates the nucleotide repeat structure; other proteins, including the *DKC1* gene product dyskenin, are associated with the telomere repair complex. Systematic surveys of DNA disclosed first *TERC* and later *TERT* mutations in some patients with apparently acquired AA, including older adults.[5] Family members who share the mutation, despite normal or near normal blood counts, have hypocellular BMs, reduced CD34 cell counts and poor hematopoietic colony formation, increased hematopoietic growth factor levels, and of course short telomeres; however, their clinical presentation is much later than in typical DKC, and they lack typical physical anomalies. Chromosomes are also protected by several proteins that bind directly to telomeres. Mutations in the gene for shelterin, one such protein, produces very severe DKC, and polymorphisms in *TERF1* and *TERF2* are also more or less prevalent in AA compared with healthy control participants. A few patients with apparently acquired AA have heterozygous mutations in the Shwachman-Bodian-Diamond syndrome *(SBDS)* gene. Almost all children with this form of constitutional AA are compound heterozygotes for mutations in *SBDS,* and their WBCs have extremely short telomeres; however, the *SBDS* gene product has not been directly linked to the telomere repair complex or to telomere binding. A parsimonious inference from these data is that inherited mutations in genes that repair or protect telomeres are genetic risk factors in acquired AA, probably because they confer a quantitatively reduced hematopoietic stem cell compartment that may also be qualitatively inadequate to sustain immune-mediated damage. Accelerated telomere attrition in AA not currently explicable by mutations may be caused by more subtle genetic lesions or follow from the pathophysiology of BM stress and excessive stem cell turnover.

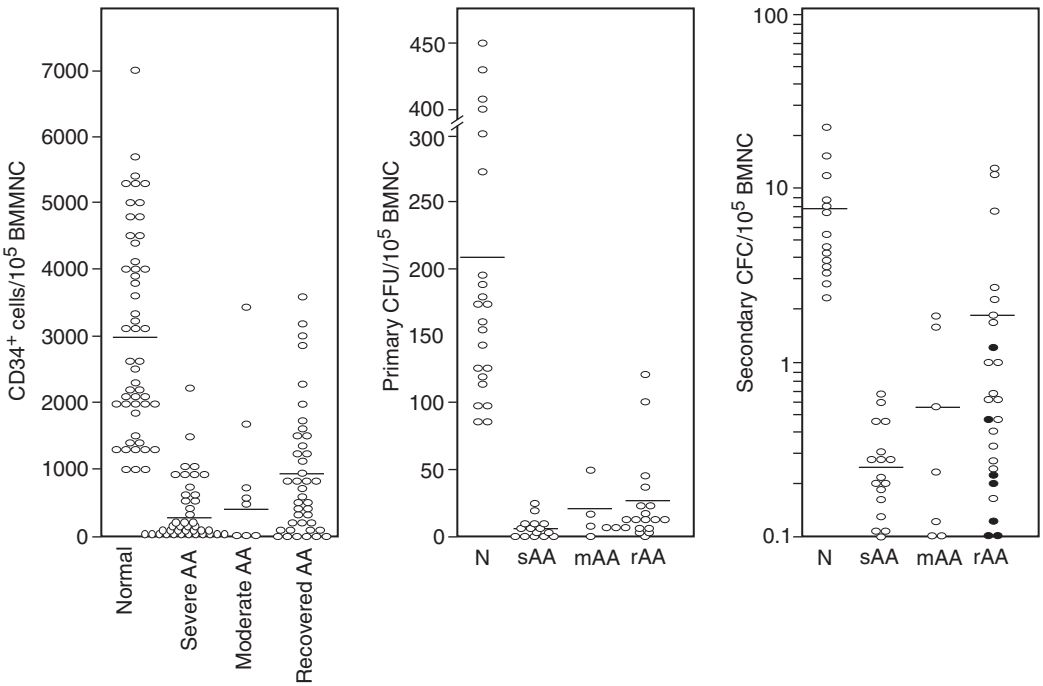

Figure 28-3 The numbers of CD34 cells, primary colony-forming cells (CFCs), and long-term culture-initiating cells (LTC-ICs) were measured in the bone marrow of patients with aplastic anemia. Each *dot* represents an individual patient's sample studied. Severe aplastic anemia (sAA) includes patients at presentation, cases refractory to immunosuppressive therapy, and patients who relapsed after a period of recovery. Primary CFCs were measured in short-term methylcellulose cultures. Secondary CFCs after long-term bone marrow cultures reflect LTC-IC numbers. *BMNC,* Blood mononuclear cell; *CFU,* colony-forming unit; *mAA,* moderate aplastic anemia; *N,* normal; *rAA,* recovered from aplastic anemia.

Stromal and Hematopoietic Growth Factors

Stromal cell function is usually not defective in cases of AA. Whereas adherent cells from patients support hematopoiesis by normal CD34 cells, no hematopoietic colonies develop when patients' CD34 cells are cultured in the presence of normal stroma (Fig. 28-4). Stromal cells cultured from patients' BM generally produce normal quantities of hematopoietic growth factors. Serum levels of erythropoietin, thrombopoietin, granulocyte colony-stimulating factor (G-CSF), and granulocyte-macrophage colony-stimulating factor (GM-CSF) are almost always normal or elevated. Cytokines that act at very early stages of hematopoiesis have been studied as possible etiologic factors in the pathobiology of AA. Blood levels of FLT3 ligand are highly elevated in AA, stem cell factor (SCF) levels are modestly decreased, and SCF stromal cell production is normal. Adequate stromal function is implicit in the success of BM transplantation (BMT) in AA because important stromal elements remain of host origin.

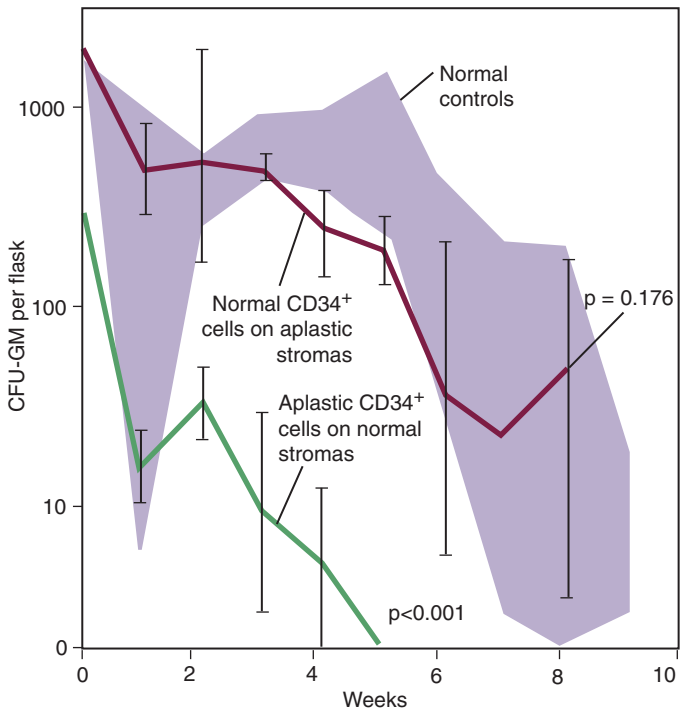

Figure 28-4 NORMAL STROMAL CELL FUNCTION IN LONG-TERM CULTURE OF APLASTIC ANEMIA BONE MARROW. *AML,* Acute myelogenous leukemia; *MDS,* myelodysplastic syndrome. *(Courtesy Dr. Judith Marsh, St. George's Hospital Medical School, London.)*

PATHOPHYSIOLOGIC PATHWAYS LEADING TO APLASTIC ANEMIA

Direct Hematopoietic Injury

The most common form of AA is iatrogenic; transient BM failure often follows treatment with cytotoxic chemotherapeutic drugs or irradiation (Fig. 28-5). Certain chemical or physical agents directly injure proliferating and quiescent hematopoietic cells. However, patients with community-acquired AA rarely have a history of exposure to such physicochemical agents. Even benzene, which can act as a particularly inefficient cytotoxic chemical, is an infrequent cause of AA in developed countries.[3] Medical drugs are associated with acquired AA, and in some instances, they can directly cause BM

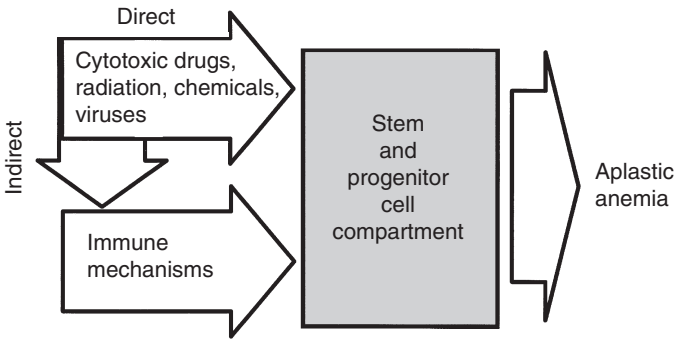

Figure 28-5 POSSIBLE CAUSES OF DIRECT AND INDIRECT BONE MARROW FAILURE IN PATIENTS WITH APLASTIC ANEMIA.

damage. However, compared with chemotherapeutic agents, which are delivered in high doses, relatively low total quantities of ingested drug apparently cause idiosyncratic hematologic reactions. In addition to their direct toxic effects, chemicals and viruses may induce complex and not well understood immune reactions leading to BM failure in persons with AA (see Fig. 28-5).

Immune-Mediated Bone Marrow Failure

In the 1970s, Mathé and colleagues observed unexpected improvement of pancytopenia after failed BMT. They speculated that the immunosuppressive conditioning regimen, intended to allow engraftment of the donor BM, might instead have promoted the recovery of host BM function. The effectiveness of diverse treatments that reduce lymphocyte number or block T-cell function and the superior results obtained when agents are combined strongly suggest that such therapeutic success is caused by the immunosuppressive effects of the drugs employed. AA shares clinical and pathophysiologic features with other autoimmune disorders that all are characterized by T-cell–mediated, tissue-specific organ destruction. Like AA, these disorders tend to occur in younger persons and show geographic variation in incidence. The late immune events that dominate at the time of clinical presentation—cytotoxic lymphocyte activation, cytokine production, and specific target cell elimination—are common to many autoimmune disorders.

Immune system destruction of BM occurs in animal models of graft-versus-host disease (GVHD) and in humans with transfusion-associated GVHD, in which AA is the invariable cause of death. Very small numbers of effector cells, which have been conveyed by residual lymphocytes contained within the transfusion product or with solid organ transplants, are sufficient to mediate GVHD under these conditions. AA is associated with rheumatologic syndromes, such as eosinophilic fasciitis, and with systemic lupus erythematosus (SLE). AA occasionally occurs in individuals with hypogammaglobulinemia or congenital immunodeficiency syndrome, thymoma, thymic hyperplasia, and thymic carcinoma.

Laboratory support for the immune hypothesis first came from coculture experiments in which mononuclear cells from AA patients' blood or BM were shown to suppress in vitro colony formation by hematopoietic progenitor cells. Removal of T cells from the patient samples sometimes improved colony formation in vitro. Peripheral blood and BM samples from patients were shown to produce a soluble factor that inhibited hematopoiesis, ultimately identified as IFN-γ. Patients' T cells overproduce IFN-γ and TNF, two cytokines that inhibit hematopoietic proliferation. Tbet, a transcriptional regulator that is critical to Th1 polarization, is constitutionally expressed in a majority of AA patients. AA blood and BM also contains elevated numbers of activated cytotoxic lymphocytes, and activity and levels of these cytotoxic cells decreased appropriately with antithymocyte globulin (ATG) therapy.

Interferon-γ and TNF negative effects on the proliferation of early and late hematopoietic progenitor and stem cells is far more potent when these cytokines were secreted into the BM microenvironment than when they were simply added to the cultures, IFN-γ and TNF can suppress hematopoiesis by effects on cell proliferation, but they also induce cell death by induction of Fas-mediated apoptosis. Immune-mediated cell cycle blockade and apoptosis can lead to the dramatic elimination of hematopoietic progenitor and stem cells in patients with AA.

The early immune system events that must precede the global destruction of hematopoietic cells are not clear. Involvement of CD4 lymphocytes has been suggested based on the overrepresentation of HLA-DR15 among patients with immune-mediated AA. Clones of HLA-DR–restricted T cells derived from a few patients have been shown to proliferate in response to BM cells.[7]

Many features of human AA can be reproduced in mouse models of GVHD in which the donor inoculum lacks stem cells. Major and minor histocompatibility mismatch demonstrates the efficacy of small numbers of T cells in specifically eliminating hematopoiesis, the role of type cytokines, the efficacy of immunosuppressive therapies, an "innocent bystander effect," and roles for specific lymphocyte regulatory and effector T-cell subsets.[8]

Radiation

Marrow aplasia is a major acute toxic effect of radiation (Fig. 28-6). The dose-related occurrence of pancytopenia 2 to 4 weeks after exposure to radiation is caused by injury of actively replicating progenitor cells. Mortality from hematologic toxicity is a function of the BM's ability to tolerate depletion of hematopoietic cells and damage to the stem cell. The capacity for recovery of hematopoietic function after even massive single irradiation exposures is considerable, reflecting the resistance of the quiescent stem cell to damage and the enormous BM repopulating potential of even a greatly reduced stem cell pool. At intermediate radiation doses around the median lethal dose (LD50), at which BM toxicity limits survival, supportive efforts can drastically alter outcome. Autopsies of atomic bomb victims in Japan showed acellular BMs in the first weeks of the explosion, but there frequently was regenerating BM in those who survived longer. The histologic picture of radiation-mediated aplasia includes necrosis, nuclear pyknosis and karyorrhexis, nuclear lysis, and ultimately cytolysis; the associated phagocytosis, marked congestion, and hemorrhage are rapidly followed by fatty replacement. BM hypoplasia occurs with radiation doses higher than 1.5 to 2 Gy to the whole body. Precise LD50 figures for humans do not exist, and estimates are based on the limited direct human data and extrapolation from animal experiments. The LD50 is highly dependent on the quality of medical care, and improved support may double the tolerated radiation dose. From assessment of the outcome of radiation accidents and high-dose therapeutic irradiation, the LD50 has been estimated at approximately 4.5 Gy (see Fig. 28-6).

Although the principles of management of pancytopenia after a single large dose of irradiation are similar to those for treating AA in general, some unique points should be made concerning immediate evaluation and long-term prognosis. The type and intensity of the source of radiation and the distance and shielding of the subject are the major determinants of radiation injury; because of the nature of the exposure, these factors are often difficult to assess. Early recognition of the nature of the accident provides the best opportunity for dosimetry by accident reconstruction and can allow employment of blocking, displacement, or chelation agents. Exposure correlates well with the degree of pancytopenia. Because lymphocytes are particularly sensitive to radiation, their rate of decline can be used to estimate the dose of total-body exposure to a level of approximately 3 Gy. At higher doses, the fall in granulocytes and the severity of thrombocytopenia and reticulocytopenia can be used as gauges. The survival of some patients who received doses higher than 9 Gy suggests in retrospect that autologous BM reconstitution may occur in most persons who survive the immediate consequences of radiation exposure.

Pancytopenia may be a late consequence of a single radiation dose, but AA is not well documented as a delayed event after radiation

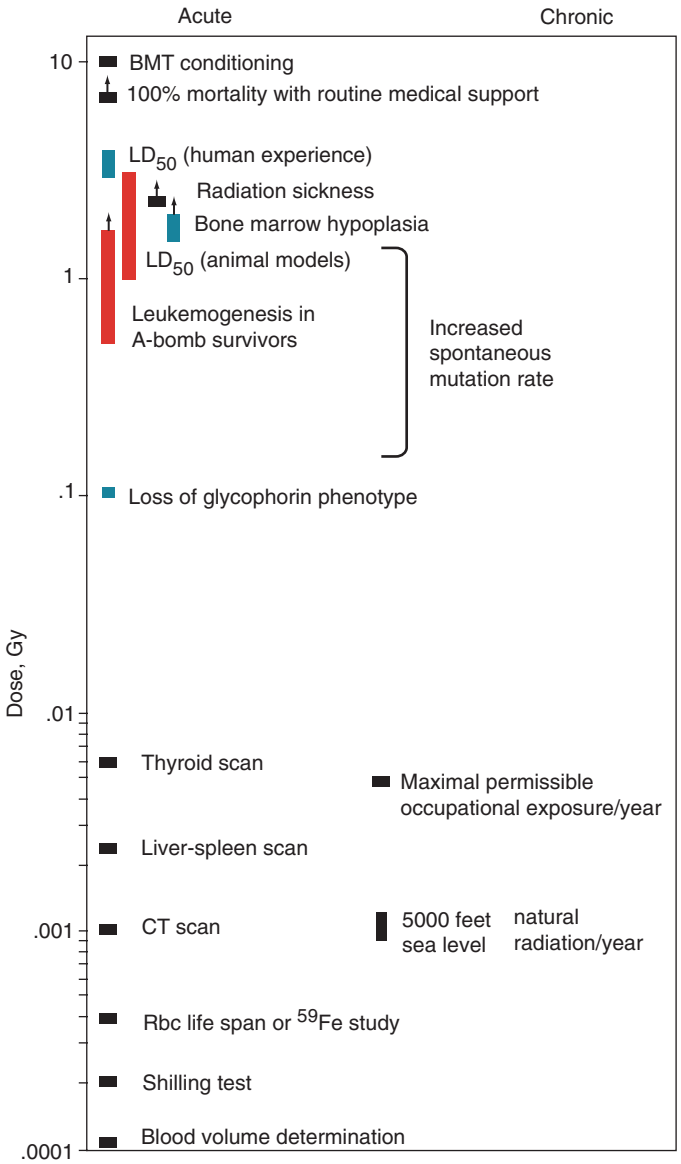

Figure 28-6 SCALE OF WHOLE-BODY RADIATION DOSES. A Gray (Gy) is a measure of absorbed dose equivalent to 1 J/kg unit mass, and 1 Gy equals 100 rads. Radiation represents radiant energy. When absorbed by biologic tissue, radiant energy causes release of electrons and molecular ionization, which result in further energy release. Radiant energy can directly break chemical bonds and indirectly damage macromolecules through generation of high-energy free radical forms. The relationship between increased mutation rate and radiation dose is very approximate *(hatched bars).* Measurement of the phenotype of an autosomal recessive gene such as for glycophorin would be expected to be a very sensitive indicator. Because malignant transformation is almost certainly a two-step process, increased leukemogenesis is probably an underestimation of the effect of radiation on a single gene. Even the extensive data on the atomic bomb survivors of Hiroshima are subject to statistical errors because of the small number of cases; a linear or exponential curve fit gives various results, and very high doses of radiation may not be associated with as high a risk of leukemia because of stem cell death. Other data that can bear on mutation frequency lie outside the range shown. In a patient with ankylosing spondylitis who underwent irradiation of the spine, leukemogenesis was observed at relatively low doses (doubling of the leukemia rate can be extrapolated to approximately 7 Gy), but such individuals can be predisposed to leukemia. An increased risk of thyroid cancer after irradiation of the mediastinum in childhood occurred at approximately 4 Gy. *BMT,* Bone marrow transplantation; *CT,* computed tomography; LD_{50}, median lethal dose; *RBC,* red blood cell.

exposure. A variety of hematologic abnormalities are associated with chronic low-level radiation exposure, most commonly lymphocytosis, neutropenia, immature or dysmorphic WBCs, and giant platelets (see Fig. 28-6). Cytogenetic abnormalities accumulate with time after chronic exposure, but they may not be reliably related to dose. Repeated low doses of radiation can damage BM and have been associated with AA, but even in these circumstances, only a small proportion of exposed individuals develop hematologic disease. AA does not appear to be more frequent among nuclear power plant or thorium processing factory workers or among residents living close to the plants. Excessive numbers of deaths from AA were reported after therapeutic irradiation of the spine for ankylosing spondylitis, later analysis has suggested that the risk may have been overestimated. AA has not been found in unexpected numbers in a large population of cancer patients who had received therapeutic irradiation. BM failure has not been observed with abnormally high frequency among persons exposed to higher natural background radiation.

Drugs and Chemicals

Aplastic anemia is frequently associated with medical drug use (Table 28-3). At the end of the 19th century, chemicals were linked to BM function through observations of benzene effects on workers. Establishment of a relationship between the analgesic amidopyrine and agranulocytosis in the early 20th century, and an apparent epidemic of AA after the introduction of chloramphenicol in the 1960s also supported this concept. Initially suggested by the accumulation of case reports, drug associations have been established in formal case-control population-based epidemiologic studies. In the IAAAS, relative risks were estimated for individual drugs and large classes of pharmaceutical agents, including nonsteroidal antiinflammatory drugs (NSAIDs), drugs affecting thyroid function, certain cardiovascular agents, some psychotropics, and sulfa-based antibiotics (Table 28-4).[3] Approximately 25% of the cases of AA identified in the IAAAS could be attributed to drug use. Drug use as a risk factor was also assessed by similar methods in Thailand, where the incidence of AA is higher than in the West. Surprisingly, chloramphenicol was not shown to be a risk factor; the etiologic fraction for drugs in AA was only 15%.

Associations between drug exposure and AA can be divided into two classes. Drugs used in cancer chemotherapy are selected for their cytotoxicity, and their regular, dose-dependent induction of BM aplasia is an expected effect. Most AA associated with medical drug use in the community is described as idiosyncratic, meaning that its occurrences are unexpectedly rare. Many of the drugs implicated in AA also appear to cause other, milder forms of BM suppression such as neutropenia. Although difficult to prove, some dose relationship probably does exist even for idiosyncratic reactions. In most case reports, patients received normal or high doses of the agent, usually for a period of weeks to months. Drug-induced aplasia cannot be distinguished by history from idiopathic forms of the disease; the clinical course, including the favorable response to immunosuppressive therapy, of patients with histories of drug exposure is the same as in idiopathic disease.

The low probability of developing AA after a course of drugs may be a reflection of the gene frequency for metabolic enzymes (for direct chemical effects) or immune response genes (for immune-mediated BM failure) in the population.[9] The rarity of idiosyncratic drug reactions could then arise from the infrequent combination of unusual circumstances: exposure, genetic variations in drug metabolism, the physical properties of the agent, enzymatic pathways that chemically alter the drug, and the susceptibility of the host to the action of a toxic compound. Many drugs and chemicals, especially if they have limited water solubility, must be enzymatically degraded before conjugation and excretion. Degradative pathways for xenobiotics are complex, specific, redundant, and interrelated. Intermediate metabolites in complex degradation pathways can be toxic, highly reactive, and responsible for some adverse effects of the primary agents. Examples of detoxifying enzyme systems directly applicable

Table 28-3 Classification of Drugs and Chemicals Associated With Aplastic Anemia

I. Agents That Regularly Produce Bone Marrow Depression as a Major Toxic Effect When Used in Commonly Used Doses or Normal Exposures

Cytotoxic drugs used in cancer chemotherapy
Alkylating agents (busulfan, melphalan, cyclophosphamide)
Antimetabolites (antifolic compounds, nucleotide analogs) antimitotics (vincristine, vinblastine, colchicine)
Some antibiotics (daunorubicin, doxorubicin [Adriamycin])
Benzene (and less often benzene-containing chemicals: kerosene, carbon tetrachloride, Stoddard solvent, chlorophenols)

II. Agents Probably Associated With Aplastic Anemia But With a Relatively Low Probability Relative to Their Use

Chloramphenicol
Insecticides
Antiprotozoals (quinacrine and chloroquine)
Nonsteroidal antiinflammatory drugs (including phenylbutazone, indomethacin, ibuprofen, sulindac, diclofenac, naproxen, piroxicam, fenoprofen, fenbufen, aspirin)
Anticonvulsants (hydantoins, carbamazepine, phenacemide, ethosuximide)
Gold, arsenic, and other heavy metals such as bismuth and mercury
Sulfonamides as a class
Antithyroid medications (methimazole, methylthiouracil, propylthiouracil)
Antidiabetes drugs (tolbutamide, carbutamide, chlorpropamide)
Carbonic anhydrase inhibitors (acetazolamide, methazolamide, mesalazine)
D-Penicillamine
2-Chlorodeoxyadenosine

III. Agents More Rarely Associated With Aplastic Anemia

Antibiotics (streptomycin, tetracycline, methicillin, ampicillin, mebendazole and albendazole, sulfonamides, flucytosine, mefloquine, dapsone)
Antihistamines (cimetidine, ranitidine, chlorpheniramine)
Sedatives and tranquilizers (chlorpromazine, prochlorperazine, piperacetazine, chlordiazepoxide, meprobamate, methyprylon, remoxipride)
Antiarrhythmics (tocainide, amiodarone)
Allopurinol (can potentiate marrow suppression by cytotoxic drugs)
Ticlopidine
Methyldopa
Quinidine
Lithium
Guanidine
Canthaxanthin
Thiocyanate
Carbimazole
Cyanamide
Deferoxamine
Amphetamines

Table 28-4 Drugs Associated With Aplastic Anemia in the International Aplastic Anemia and Agranulocytosis Study*

Drug	Stratified Risk Estimate (95% CI)	Multivariate Relative Risk Estimate (95% CI)
Nonsteroidal Analgesics		
Butazones	3.7 (1.9-7.2)	5.1 (2.1-12)
Indomethacin	7.1 (3.4-15)	8.2 (3.3-20)
Piroxicam	9.8 (3.3-29)	7.4 (2.1-26)
Diclofenac	4.6 (2.0-11)	4.2 (1.6-11)
Antibiotics		
Sulfonamides†	2.8 (1.1-7.3)	2.2 (0.6-7.4)
Antithyroid drugs	16 (4.8-54)	11 (2.0-56)
Cardiovascular Drugs		
Furosemide	3.3 (1.6-7.0)	3.1 (1.2-8.0)
Psychotropic drugs		
Phenothiazines	3.0 (1.1-8.2)	1.6
Corticosteroids	5.0 (2.8-8.9)	3.5 (1.6-7.7)
Allopurinol	7.3 (3.0-17)	5.9 (1.8-19)
Gold	29 (9.7-89)	

From Kaufman DW, Kelly JP, Levy M, et al: *The drug etiology of agranulocytosis and aplastic anemia.* New York, 1991, Oxford University Press.
CI, Confidence interval.
*The multivariate model included the following factors: age, gender, geographic area, date of interview, reliability of the patient, person interviewed, transfer from another hospital, history of blood disorder or tuberculosis, exposure to benzene and related chemicals, and use of other suspected drugs.
†Other than trimethoprim–sulfonamide combination.

to BM failure and that also demonstrate genetic variability include arylhydrocarbon hydroxylase (e.g., benzene toxicity), epoxide hydrolases (e.g., phenytoin toxicity), *S*-methylation (e.g., 6-mercaptopurine, 6-thioguanine, azathioprine), and *N*-acetylation (e.g., sulfa drugs). Genomic approaches have revealed the complex role of genetic variation in metabolic pathways that process arylhydrocarbons and even links to the immune function.

Benzene

Benzene exposure is linked to AA. Benzene myelotoxicity can be placed between the predictable effects of chemotherapeutic agents and idiosyncratic drug reactions. Industrial emissions add greatly to the biologic sources of ambient benzene. Significant benzene exposure can also occur outside of industry. Although the concentrations of benzene to which consumers are exposed are orders of magnitude lower than those observed in industrial workers, the effect of low-dose chronic exposure is uncertain, but genetic variations in the metabolizing enzymes may influence susceptibility to BM suppression at these levels. Benzene metabolites are also generated from the diet.

Water-soluble products of benzene metabolism such as phenols, hydroquinones, and catechols mediate the toxicity to the BM. Benzene and its intermediate metabolites covalently and irreversibly bind to BM DNA, inhibit DNA synthesis, and introduce DNA strand breaks. Benzene acts as a "mitotic poison" and as a mutagen. Acutely, the more mature, actively cycling BM precursor cells are preferentially damaged over the more primitive progenitors. Intermittent exposure may be more damaging to the stem cell compartment than is continuous exposure. BM stroma can also be damaged by benzene.

The range of hematologic disease attributable to benzene is broad, from relatively frequent mild alterations in blood counts to AA or leukemia. Studies of exposed North American workers earlier in the 20th century suggested that the risk of AA was 3% to 4% in men exposed to concentrations higher than 300 ppm and that 50% of individuals exposed to 100 ppm developed some blood cell count depression. The prevalence of some form of BM suppression, manifest as leukopenia, for example, with heavy exposure can be high. Leukopenia, anemia, thrombocytopenia, and lymphocytopenia are common consequences of benzene; other manifestations include macrocytosis, acquired Pelger-Huet anomaly, eosinophilia, and basophilia and less often, polycythemia, leukocytosis, thrombocytosis, or splenomegaly. The BM is usually normocellular but can show hypocellularity or hypercellularity; a hypercellular phase can precede complete aplasia. In addition to hypocellularity, chronically exposed workers can have BM necrosis, fibrosis, edema, and hemorrhage. Conversely, pancytopenia can precede acute leukemia. BM failure and leukemia in benzene workers can manifest decades after exposure.

Aromatic Hydrocarbons

The common perception that other molecules resembling benzene or containing a benzene ring can also cause BM suppression is not well supported. Neither the closely related alkylbenzenes nor pure toluene or xylene is an established BM toxin. Often, an aromatic hydrocarbon has been implicated as causative by a clinician only for lack of another apparent etiology. For some substances, toxicity might result from the presence of benzene as a contaminant of the synthesis of the molecule or in the petroleum distillates used to dissolve the compound. However, the total number of AA cases reported with aromatic hydrocarbon exposures is small when the large populations exposed to this heterogeneous group of chemicals are considered. For example, the significance of a handful of case reports associated with insecticide exposure in the context of the vast use of these compounds is questionable. However, the very high prevalence of aromatic hydrocarbons in daily life would greatly amplify even a small individual risk. Pesticides and insecticides have been associated with AA for decades, with almost 300 medical case reports appearing in the medical literature. The most frequently cited insecticides are chlordane, lindane, and dichlorodiphenyltrichloroethane (DDT). For the miscellaneous aromatic hydrocarbons, case reports also greatly outnumber series of patients, and systematic epidemiologic surveys have shown mixed results.

Chloramphenicol

A structural similarity of chloramphenicol to amidopyrine, a drug known to cause agranulocytosis, led to early prediction of possible hematotoxicity. During the period of its unrestrained use, chloramphenicol was considered the most common cause of AA in the United States, accounting for 20% to 30% of total cases and 50% of drug-associated cases. Estimates of the risk of AA after a course of chloramphenicol ranged from one case per 20,000 to one case per 800,000 people. Based on these figures, a course of chloramphenicol was estimated to increase the risk of AA 13-fold. Although the introduction of chloramphenicol into the American market was perceived as having increased the total number of cases of AA, this assumption was only weakly supported by epidemiologic data, and the mortality rate from AA remained essentially constant during the period of chloramphenicol's introduction and extensive use and after the withdrawal of chloramphenicol from the market. Chloramphenicol has not been associated with AA in Thailand despite its high rate of use there. In Hong Kong, where the use of chloramphenicol is almost 100 times higher than in the West, drug-associated AA occurs infrequently. The early epidemiologic surveys stressed excessive dosage, high blood levels, repeated or intermittent courses, young age, and oral route of administration as particular risks for chloramphenicol BM toxicity.

At ordinary doses, a pattern of reversible alterations in erythropoiesis occurs in most patients treated with chloramphenicol. In vitro, chloramphenicol can decrease hematopoietic colony formation[3] or diminish colony size, although usually at doses greater than those achieved in patients. There is no consistent evidence of abnormal BM sensitivity to the drug in affected individuals.

Nonsteroidal Antiinflammatory Drugs

Compared with chloramphenicol, it took far longer to associate phenylbutazone with AA. Mortality estimates have ranged from one case per 100,000 to one case per 1 million treatment courses. The use of other NSAIDs is associated with case reports of AA. A large case-control led investigation in Europe confirmed the risk of AA with phenylbutazone use and identified even higher probabilities with other NSAIDs. There was a suggestion of increased risk with drugs taken regularly for a prolonged period at very high doses, and in some cases, hematologic reactions were reproduced on repeat exposure.

Neuroleptics and Psychotropic Drugs

A variety of drugs used to treat disorders of the central nervous system have been associated with AA: the hydantoins and carbamazepine, antidepressants, tranquilizers, and felbamate. The marketing of felbamate was severely affected by the occurrence of aplasia in more than 30 patients. Monitoring of drug blood levels and peripheral blood counts in patients receiving carbamazepine was recommended despite fewer than two dozen AA cases reported by 1982. Doubt about the validity of many cases reported in the literature, as well as several large series of patients who did not develop hematologic toxicity and an estimated AA case rate of approximately one in 200,000 treated patients, have led to questions concerning the relationship between carbamazepine and AA.

Gold and Heavy Metals

Gold salts have an extraordinarily high frequency of fatal adverse reactions, estimated at 1.6 cases per 10,000 prescriptions. Dose-dependent leukopenia is common, but several dozen cases of AA have been reported. In the IAAAS, exposure to gold salts was the most significant drug association for developing AA, with a relative risk of 29 and an excess risk of 23 cases per 1 million users in 1 week.[3] Spontaneous recovery rarely occurs. Patients have been successfully treated with stem cell transplantation or immunosuppressive therapy; chelation therapy usually has not been helpful. High concentrations of gold salts inhibit hematopoietic colony formation in vitro; there is some evidence for a dose relationship.

TYPICAL AND ATYPICAL PRESENTATIONS

Most patients with AA seek medical attention for symptoms that occur as a result of low blood counts (Table 28-5 and Fig. 28-7). Some patients can be diagnosed incidentally and show remarkable few symptoms despite severely depressed blood counts. All of the blood elements can be depressed or a single lineage cytopenia can dominate the clinical picture. The differential diagnosis of pancytopenia includes a variety of diseases (see Table 28-1). Most patients do not have systemic symptoms; weight loss, persistent fever, pain, and loss of appetite point to an alternative diagnosis.

Bleeding is the most alarming manifestation of pancytopenia and most frequently sends the patient to a doctor. Thrombocytopenia usually does not cause massive bleeding. Instead, the patient reports easy bruisability and the appearance of red spots, especially over dependent surfaces; gum bleeding with tooth brushing and episodic nose bleeds are common. Heavy menstrual flow or irregular vaginal bleeding can occur in younger women. In AA associated with PNH, red or dark urine may be reported that is caused by free hemoglobin, but visible bleeding from the genitourinary and gastrointestinal tracts

Table 28-6 Severity of Aplastic Anemia as Defined by Laboratory Studies

Severe aplastic anemia
Bone marrow cellularity <30% Two of three peripheral blood criteria: Absolute neutrophil count<500 cells/mm^3 Platelet count <20,000 cells/mm^3 Reticulocyte count <40,000 cells/mm^3
No other hematologic disease
Moderate aplastic anemia
Patients with pancytopenia who do not fulfill the criteria of severe disease

Diagnostic Algorithm in Aplastic Anemia

AA, Aplastic anemia; *AML,* acute myeloid leukemia; *AMM,* agnogenic myeloid metaplasia; *BM,* bone marrow; *DEB,* diepoxybutane; *MDS,* myelodysplastic syndrome; *MMC,* mitomycin C; *PB,* peripheral blood.

is rare on presentation in AA. Extensive hemorrhage from any organ can occur but usually late in the course of the disease and almost always associated with infections, drug therapy (e.g., corticosteroids), or invasive procedures.

The ability to adapt to a gradual reduction in hemoglobin concentration is remarkable. Patients with anemia might mention fatigue, lassitude, shortness of breath, or ringing in the ears, but some individuals can tolerate astonishingly low hemoglobin levels without complaint. Even abrupt cessation of erythropoiesis leads to only a slow decline in hemoglobin (≈1 g/dL each week).

Infection is an uncommon presentation in patients with AA. The sore throat of agranulocytosis is not often observed, presumably because other alarming symptoms appear earlier.

Retrospective studies of AA associated with drugs and viruses and the observation of the occasional patient with serially monitored blood counts suggest a latent period of 6 to 8 weeks between the inciting event and the onset of pancytopenia. The interval can be more prolonged when pancytopenia is well tolerated or moderate. For purposes of diagnosis and management, a history of blood diseases in other family members is very important and should trigger appropriate genetic tests for constitutional causes.

With identification of genetic risk factor, the family history has assumed great importance in the evaluation of pancytopenia. Leukemia and myelodysplastic syndrome (MDS) can occur in FA and DKC pedigrees. In the telomeropathies secondary to *TERT* and *TERC* mutations, hematologic findings in other family members may be mild, such as modest thrombocytopenia or macrocytosis with or without anemia. These mutations also are etiologic of cirrhosis and pulmonary fibrosis, which may be present as diagnoses in the pedigree. Early graying of the hair is a less reliable sign but is sometimes prominent in the telomere diseases.

Findings on physical examination usually reflect the severity of the pancytopenia (Table 28-6). However, patients with severe disease can look well. The patient may present with subtle variations from normal or with a dramatic, even toxic appearance. Petechiae are often present over the pretibial surface of the lower leg and the dorsal aspects of the forearm and wrist; a few petechiae can be seen in the oropharynx and on the palate. Scattered ecchymoses typically appear in areas exposed to minor trauma. With severe thrombocytopenia, retinal hemorrhages can be present on funduscopic examination, there can be gingival oozing or blood in the nares, and hemorrhage can be apparent at the uterine cervical os. The stool can contain traces of heme. Pallor is common and is best appreciated on the mucosal membranes and palmar surfaces. A new patient can be febrile, but specific or localizing signs of infection are uncommon on presentation. Cachexia, splenomegaly, and lymphadenopathy are not associated with AA, and these findings should strongly suggest another diagnosis. The examiner should look carefully for café au lait spots and other physical anomalies of FA and for typical nail changes, leukoplakia, hypopigmentation of the skin, and grey hair of telomere disease in children *and* adults.

Several atypical presentations of AA should be pointed out. A physician might encounter an elderly patient with pancytopenia in

Table 28-7 Bone Marrow Morphologic Findings that Discriminate Myelodysplasia From Aplastic Anemia

Characteristic*	Myelodysplasia	Aplastic Anemia
Cellularity	Usually normal to increased	Decreased
Erythropoiesis		
Megaloblastic	Very common	Common
Dyserythropoietic	Very common	Unusual
Maturation defects	Common	Not found
Ringed sideroblasts	Common	Not found
Myelopoiesis		
Monocyte prominence	Very common	Unusual
Midmyeloid predominance	Very common	Unusual
Increased blasts	Yes	Not found
Megakaryocytes		
Atypical morphology	Very common	Not found

Adapted from Bagby GC: The preleukemic syndrome (hematopoietic dysplasia). In Shahidi NT, editor: *Aplastic anemia and other bone marrow failure syndromes,* New York, 1990, Springer-Verlag, p 199. Provides percentages for myelodysplasia.
*Ringed sideroblasts and myeloblasts are observed by definition in some of the myelodysplastic syndromes. Dyserythropoietic red blood cell precursors show bizarre forms with multiple or irregular nuclei. Megakaryocytes can show defective nuclear polyploidization and increased internuclear spaces, or they can be small with only a few nuclei and peculiar granulation.

whom subsequent BM examination reveals dysplastic features (see box on Diagnostic Algorithm in Aplastic Anemia and Table 28-7). Although the history of the illness in a newly diagnosed patient is typically short—in the range of months—some patients may recall a long history of bruisability, anemia, and low blood cell counts reported to them by previous physicians during routine examinations. These patients can have a moderately severe, chronic disease that is stable for years, and pancytopenia from childhood should suggest a constitutional AA.

CLINICAL ASSOCIATIONS

A number of clinical syndromes, usually revealed through a careful history and physical examination, are associated with AA (see box on Diagnostic Algorithm in Aplastic Anemia and Tables 28-2 and 28-3).

Posttransfusion Graft-Versus-Host Disease

Almost uniformly fatal, AA is a constant feature of transfusion-associated GVHD produced by the transfusion of competent lymphocytes into immunodeficient hosts, including children with congenital syndromes, cancer patients receiving high-dose chemotherapy, and patients with adoptive cellular immunotherapy for leukemia. Rarely, posttransfusion GVHD occurs in an apparently immunocompetent recipient in the special circumstance in which the donor is homozygous for an HLA haplotype also shared by the recipient, as can occur among first-degree family members. Small numbers of lymphocytes are sufficient to produce the syndrome, which is surprisingly resistant to immunosuppressive therapy. Pancytopenia with BM hypoplasia is an almost constant feature of posttransfusion GVHD. Runt disease in animals is a model of this immune-mediated BM failure syndrome.

Pregnancy

Pregnancy is common in the age groups most susceptible to BM failure, and in many cases, its association is probably only coincidental. The true frequency of AA in pregnancy is unknown, but from the number of cases reported, it appears rare, although BM hypoplasia may be relatively common during pregnancy. A causal relationship is suggested by the temporal relationship between the onset of pancytopenia and that of pregnancy and by resolution after delivery and spontaneous or induced abortion; some patients have developed AA that remitted after each delivery. Survival rates for AA in pregnancy have been relatively high for the mother and baby, with most pregnancies being successful. Hemorrhage is the most common cause of death from AA during pregnancy. The published data are insufficient to guide the management of pregnant women with AA, especially because it is clear that AA in some cases is serendipitously diagnosed and can persist beyond parturition. A woman who desires a child can be maintained with transfusions with the understanding that any clinical deterioration is a criterion for interruption or termination of the pregnancy. The hazard of pregnancy to a woman who has recovered from idiopathic AA is unknown, but most hematologists, recognizing the risk of relapse, advise patients not to become pregnant, especially if thrombocytopenia and a PNH clone are present.[10]

Post-Hepatitis AA

Hepatitis-associated AA has several peculiar features. Typically, an uneventful episode of apparent viral hepatitis in a young man is followed in 1 to 2 months, during convalescence from the liver inflammation, by very severe pancytopenia. Depression of blood cell counts during the course of hepatitis is common; leukopenia, atypical lymphocytosis, erythroid macrocytosis, and thrombocytopenia mimic in milder forms the hematologic changes of AA. However, posthepatitis AA has a very poor prognosis, with early estimates of mortality of 90% at 1 year, and a history of hepatitis in AA has been considered an indication for early BMT. Patients with posthepatitis AA can successfully undergo BMT without an increased risk of veno-occlusive disease. Patients with hepatitis-associated aplasia have markers of immune system activation and respond well to intensive immunosuppressive therapy. Almost all cases have been seronegative, non-A, non-B, and non-C hepatitis. Posthepatitis AA is linked to fulminant hepatitis of childhood and acute seronegative hepatitis. Acute viral hepatitis that is seronegative differs clinically from hepatitis C disease; parenteral exposure is not a risk factor, liver functions abnormalities are more severe during the acute phase, and late complications are more common.

Postmononucleosis Aplastic Anemia

Acute infection with Epstein-Barr virus (EBV) causes infectious mononucleosis that is commonly associated with neutropenia and other hematologic abnormalities but, similar to acute hepatitis, is only rarely complicated by AA. However, EBV may be involved in the cause of AA more frequently than originally appreciated because a large number of primary EBV infections are unrecognized. Pancytopenia can be first observed during the acute mononucleosis syndrome or shortly after disappearance of symptoms. Some patients have recovered spontaneously, others after therapy with corticosteroids or immunosuppressive therapy. EBV can occasionally be demonstrated in the BM cells of patients with apparently idiopathic AA in association with serologic evidence of a primary or reactivated viral infection.

Hemophagocytic Syndrome

The BM is hypocellular in approximately one-third of cases with hemophagocytic syndrome. In this disorder, there can be progression from BM hypercellularity to aplasia; myelofibrosis is also common. Pancytopenia occurs in most of cases; anemia is a universal finding; thrombocytopenia and neutropenia are also common. In contrast to typical AA, these patients appear systemically ill, with fever and

constitutional symptoms, and peripheral blood cell count depression is often associated with abnormalities of other organ systems, including hepatosplenomegaly, lymphadenopathy, cutaneous eruptions, and pulmonary infiltrates. The syndrome is associated with a large variety of diseases, including immunodeficiency, malignancy, and infections. In the infectious category, viral infections are most common and include EBV, cytomegalovirus, herpes simplex, herpes zoster, B19 parvovirus, and HIV-1; bacterial and parasitic infections also have been associated with hemophagocytosis. Hemophagocytosis is often observed on supravital or Wright-Giemsa staining of the BM of patients with idiopathic AA, and it is also a morphologic feature of graft rejection after BMT. In virus-associated hemophagocytosis, there is evidence of immune system activation. The sera of patients have been shown to contain high levels of IFN-γ, TNF-α, IL-6, soluble CD8, and soluble interleukin-2 (IL-2) receptor, and T cells overproduce IFN-γ in vitro. The clinical response to cyclosporine is consistent with a T cell–mediated pathophysiology of hematopoietic failure.

Paroxysmal Nocturnal Hemoglobinuria and Aplastic Anemia

There is a strong association between AA and PNH (see Chapter 29). These diseases frequently are diagnosed concurrently or sequentially in the same individual, and they share similar clinical and pathologic features (i.e., pancytopenia and BM hypocellularity). The presence of an expanded PNH clone is associated with HLA-DR15 and has been reported as a good prognostic factor for the responsiveness to immunosuppressive therapy. Clinical BM failure can be present at the onset of PNH or can develop after diagnosis. By flow cytometry of granulocytes for glycosylphosphoinositol-anchored proteins, there is expansion of a PNH clone in 50% or more of AA cases at presentation.[11]

Longitudinal studies of patients with de novo PNH or PNH developing from AA indicate a low probability of spontaneous remission; in most patients, the contribution of the PNH clones remains stable for years, but hemolytic disease can develop.

Collagen Vascular Diseases

Aplastic anemia is a component of the collagen vascular syndrome called eosinophilic fasciitis. This severe, scleroderma-like disease is characterized by fibrosis of subcutaneous and fascial tissue, localized skin induration, eosinophilia, hypergammaglobulinemia, and an elevated erythrocyte sedimentation rate. The rheumatologic symptoms of fasciitis respond to corticosteroids, but the associated AA has a very poor prognosis. A few patients have survived after BMT or immunosuppressive therapy. More rarely, AA has complicated SLE and rheumatoid arthritis, but in many cases, the role of concomitant drug therapy is confounding. Rarely, AA can accompany Sjögren syndrome, multiple sclerosis, and immune thyroid disease. AA occasionally occurs in individuals with hypogammaglobulinemia or congenital immunodeficiency syndrome, thymoma, or thymic hyperplasia.

LABORATORY EVALUATION

Peripheral Blood

In typical cases of AA, all of the blood cell counts are depressed. The blood smear usually shows obvious paucity of platelets and leukocytes but normal RBC morphology; toxic granulations can be present in neutrophils. Automated cell counting shows erythrocyte macrocytosis and a normal RBC distribution of width. Platelet size is normal and not increased as in immune peripheral destruction, but the low number can cause greater heterogeneity of size. Prior transfusions alter platelet numbers, relative reticulocyte counts, and hemoglobin values. Although relative lymphocytosis is very common, most patients also have decreased absolute numbers of monocytes and lymphocytes. The severity of AA can be graded based on the peripheral blood cell counts (see Table 28-6 and box on Diagnostic Algorithm in Aplastic Anemia).

DIAGNOSIS OF APLASTIC ANEMIA

Although the ultimate diagnosis of AA rests on the interpretation of an adequate BM biopsy specimen, important clues to the cause of pancytopenia can be obtained from the history, physical examination, and laboratory data. Pancytopenia that is not primarily hematologic in origin but secondary to other disease processes is usually an obvious diagnosis. Patients with severe liver disease and splenomegaly, SLE, or overwhelming sepsis can have low blood cell counts, but their clinical presentation is not subtle. Similarly, BM aplasia follows cytotoxic drug therapy for cancers and is an anticipated and transient toxic effect for a variety of nonmalignant diseases. In challenging cases, obvious medical causes of pancytopenia usually have already been excluded. Pancytopenia almost never results from peripheral blood cell destruction alone. In AA, the blood smear does not show reticulocytes, band forms, or the large platelets typical of increased compensatory BM efforts.

Acquired AA is a disease of the young, as is constitutional aplasia. Patients with FA often, but not always, have physical abnormalities. In the absence of a suggestive family history or the presence of physical anomalies, the distinction between acquired and constitutional disease depends on the results of a clastogenic-stress culture of peripheral lymphocytes (for FA) and telomere length of leukocytes (for DKC and the telomeropathies).

In older patients, the major differential diagnosis is between AA and myelodysplasia. There is a gray area between hypocellular myelodysplasia and moderate AA, and even competent hematologists might not agree on the final diagnosis. BM cytogenetics can help in establishing the proper diagnosis.

Myelofibrosis can also produce pancytopenia, but the BM is not aspirable, the spleen is often enlarged, and the peripheral blood smear shows characteristic abnormalities. Acute leukemia in children and elderly adults can manifest as BM hypocellularity, requiring a careful search for lymphoblasts or myeloblasts, including phenotypic analysis by flow cytometry. Peripheral blood flow cytometry for glycophosphoinositol-anchored proteins should be performed to diagnose PNH (see Chapter 29).

The patient's history can provide clues, such as benzene exposure for myelodysplasia and acute leukemia or a suspicious drug history for AA. Discontinuation of exposure to the incriminated drugs or chemicals is mandatory, and in some instances, patients may then recover. However, given the difficulty of assigning blame with absolute certainty to environmental agents, the authors treat all patients similarly and do not advocate protracted observation for possible spontaneous recovery. For patients with severe disease (see Table 28-6), suitable and early preparation for BMT should be undertaken or immunosuppression begun, but for those with moderate disease, the clinical status should be evaluated, and serial blood cell counts are required to assess progression of the disease.

BONE MARROW

The BM must be assessed quantitatively and qualitatively for cellularity and the morphology of residual cells (Fig. 28-8 and see Fig. 28-1). BM aspiration and biopsy should always be performed, and the core specimen should be at least 1 cm long. There should be no compromise in obtaining adequate specimens and no hesitation in performing a second procedure if required.

Bone marrow cellularity is estimated from the core biopsy. Point counting under microscopic cross hairs in many parts of a histologic section is the most accurate method of determining cellularity, but hematologists commonly rely on visual estimation only. A crude

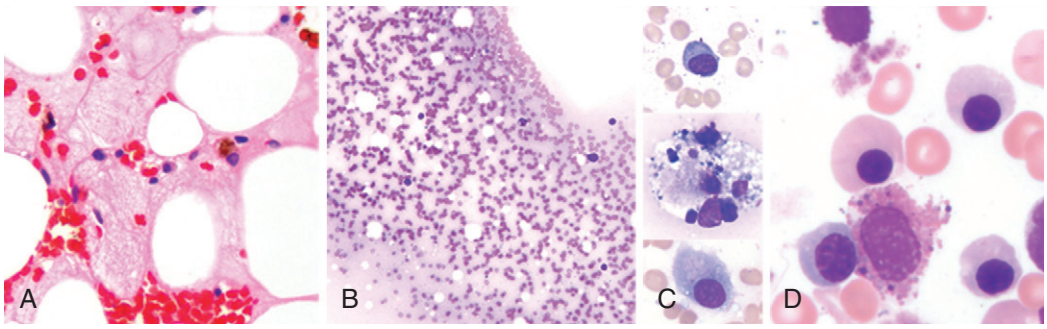

Figure 28-8 SOME MORPHOLOGIC FEATURES OCCASIONALLY OBSERVED IN PATIENTS WITH APLASTIC ANEMIA. Empty marrow with eosinophilic ground substance consistent with serous atrophy or stomal injury **(A),** possibly indicative of marrow damage. Scanty bone marrow aspirate in severe disease **(B)** showing only rare nucleated elements, many of which are from blood. The presence of plasma cells, histiocytes, and osteoblasts **(C)** confirms the bone marrow nature of the aspirate. Note: Sometimes the histiocytes can show hemophagocytosis. Megaloblastoid erythropoiesis **(D)** is sometimes seen in aplastic anemia and in recovery.

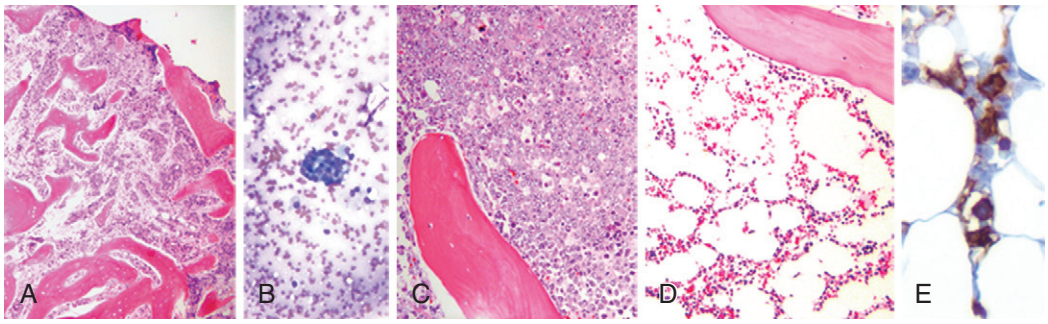

Figure 28-9 MORPHOLOGY OF OTHER DISEASES THAT MAY MANIFEST WITH PANCYTOPENIA. Bone marrow biopsy from patient with pancytopenia showing myelofibrosis and osteosclerosis associated with metastatic prostate cancer **(A).** The aspirate was hypocellular but did show occasional tumor clusters **(B).** Another case where the patient presented with pancytopenia and was found to have a bone marrow packed with lymphoma cells **(C).** Hairy cell leukemia can present with pancytopenia and with a hypocellular bone marrow **(D)** difficult to distinguish from aplastic anemia. The diagnosis rests on identifying a B-cell infiltrative process with immunohistochemical stains (**E,** CD20).

"eyeball" approximation is almost always adequate in severe aplasia because the hematopoietic content of the BM specimen is usually close to zero. Estimates of BM cellularity based on examination of the aspirate smear and biopsy specimen are correlated, but dilution of the aspirate by sinusoidal blood often occurs, and the aspirate can be hypocellular when the biopsy specimen is hypercellular or can show focal areas of active hematopoiesis. Normal BM cellularity decreases with age, a variation that is of some importance in assessing older patients with aplasia or myelodysplasia. In autopsy samples from normal young children, approximately 80% of the BM space of the iliac crest is cellular. BM cellularity gradually decreases from age 20 to 70 years and more precipitously in very elderly adults to approximately 30% in the eighth decade of life. For practical purposes, the lower limit of normal BM cellularity in adults is accepted at approximately 30%, but the differences at the extremes of life should be recalled when evaluating infants and elderly adults. In most patients with AA, total BM cellularity is extremely low, but there can be significant residual lymphocytosis. The increase in BM fat in aplasia is caused by increases in the size and number of individual fat cells. "Hot pockets" of hematopoiesis can be present. The BM tends to contract centripetally with age, and a similar process can be observed in pathologic states, so the sternal BM can be more cellular than iliac crest samples.

Examination of the BM (Fig. 28-9 and see Figs. 28-1 and 28-8) is basic for the diagnosis of most primary hematologic causes of pancytopenia (see Table 28-1 and box on Diagnostic Algorithm in Aplastic Anemia). Information can be gained by observing the BM aspirate itself. A fatty, even watery specimen can usually be aspirated without difficulty from an aplastic patient, but a truly dry tap is more typical of a hypercullular ("packed") or fibrotic BM. The morphology of individual cells is best seen in the Wright-Giemsa–stained aspirate smear, and the architecture of the BM is appreciated in a biopsy section. In acellular specimens, the only cells visible are usually lymphocytes, plasma cells, and stromal elements—fibroblastoid and histiocytic cells. Some degree of dyserythropoiesis is common, usually the megaloblastoid features of macrocytosis and some nuclear-cytoplasmic maturation asynchrony, but sometimes more complex degenerative changes in nuclei and cytoplasm can be observed by light and electron microscopy (see Fig. 28-8). These features are common to AA and myelodysplasia (see Table 28-7), which can be very difficult to distinguish. Hemophagocytosis of RBCs can also be seen in AA. Examination of the cells close to the spicules of a sparse aspirate smear can disclose a distinctive population of leukemic blasts; increased numbers of myeloblasts are not seen in AA and are evidence of aleukemic leukemia or herald the evolution of leukemia from pancytopenia. Histochemistry for CD34 cells should show staining only of vascular elements in AA, and increased CD34 is typical of MDS and AML. Lymphoid aggregates, nests of tumor cells, granulomas, and infectious particles can be apparent on examination of the fixed biopsy specimen.

Karyotyping of BM cells is diagnostically important. Unfortunately, the yield of cells from a hypocellular BM can be inadequate to perform cytogenetic analysis. Chromosome analysis is usually normal in AA but frequently reveals a clonal abnormality in myelodysplasia. Cytogenetic studies, including interphase fluorescent in situ hybridization (FISH) and single nucleotide polymorphisms array-based karyotyping may produce informative results, including detection of cryptic chromosomal abnormalities.[12]

Radiographic Measures of Bone Marrow Function

Magnetic resonance imaging (MRI) with spin-echo sequences can be useful in the study of BM disease. On T1-weighted spin-echo images, fatty BM appears bright, and cellular BM exhibits a lower density signal (Fig. 28-10). The high fat content of aplastic BM can be readily appreciated on MRI. Magnetic resonance spectroscopy, which detects the type of fat signal, has shown diverse patterns among AA patients. MRI is complementary to tissue sampling, allowing a large area of BM to be visualized and fat content to be roughly quantified. The technique appears to be worthwhile in diagnosis because the patterns of fat and cell distribution appear to differ between aplasia and hypocellular myelodysplasia, and in prognosis, to monitor improvements in hematopoiesis after treatment.

DIFFERENTIAL DIAGNOSIS OF PANCYTOPENIA

Aplastic anemia is not the most common cause of pancytopenia (see Table 28-1). A rational diagnostic algorithm can be very helpful in establishing a correct diagnosis (see box on Diagnostic Algorithm in Aplastic Anemia). Pancytopenia is unlikely to be the presenting feature of hypersplenism in cirrhosis or of Evans syndrome in SLE. Findings on physical examination can point strongly toward another diagnosis. For example, whereas patients with myelofibrosis usually have splenomegaly, a large spleen is very unusual in those with AA. Although vitamin B_{12} and folate deficiencies have been reported to be associated with erythroid hypoplasia, this must be an exceedingly rare event. For practicing hematologists, the most important and difficult choice of diagnoses in pancytopenic patients is among the primary BM disorders. An empty BM is usually obvious, but diagnostic confusion arises from the equivocal character of moderate AA; alterations in the BM appearance in patients with chronic disease; and real overlaps among AA, myelodysplasia, and leukemia.

In moderate AA, the modest depression of BM cellularity can muddle the single most reliable diagnostic criterion. BM cellularity is imprecisely quantitated at best, and further uncertainty is introduced by large sampling errors. "Hot spots" of hematopoietic activity in an otherwise acellular specimen reflect biologic heterogeneity in the pattern of cell loss. In patients with a syndrome of transient pancytopenia, spontaneous recovery occurs within a few months; although the blood cell counts can be severely depressed, the BM is much more commonly normal or hypercellular than hypoplastic. In patients with chronic BM failure, serial BM specimens may not be identical because of sampling error or because the original disease was misdiagnosed or has changed its character. Some patients with AA are not pancytopenic; they do not have uniform depressions of RBC, WBC, and platelet production, despite an empty BM, and their clinical course is dominated by failure in two cell lines or a single hematopoietic lineage. Related conditions such as pure RBC aplasia, amegakaryocytic thrombocytopenia, and agranulocytosis, although usually distinctive in their clinical presentation, can evolve into more generalized BM failure. In the absence of better markers, sometimes the only accurate diagnosis is a description of the clinical features and the specific BM morphology.

A hypocellular BM often precludes the proper morphologic diagnosis. This problem can be especially evident in the case of an MDS with hypoplastic BM (see Table 28-7).

Bone marrow cytogenetics, if positive for chromosome abnormalities, established the diagnosis of leukemia or MDS (see Chapter 27). However, some random chromosomal abnormalities may be transient, and some believe that typical AA is not incompatible with the abnormal karyotype, particularly when somatic mosaicism is present. Often, acellular specimen precludes successful culture and generation of metaphase smears. In such cases, single nucleotide polymorphisms arrays-based karyotyping can be performed on interphase cells and may be helpful in detection of clonal abnormalities.[13] Screen for monosomy-7, and trisomy-8 can also be performed using interphase FISH.

TREATMENT

Aplastic anemia should be considered a medical emergency. Lives are lost, mainly because the grave consequences of severe pancytopenia go unrecognized. The ultimate benefits of definitive therapies such as transplantation or immunosuppression will be unrealized if the

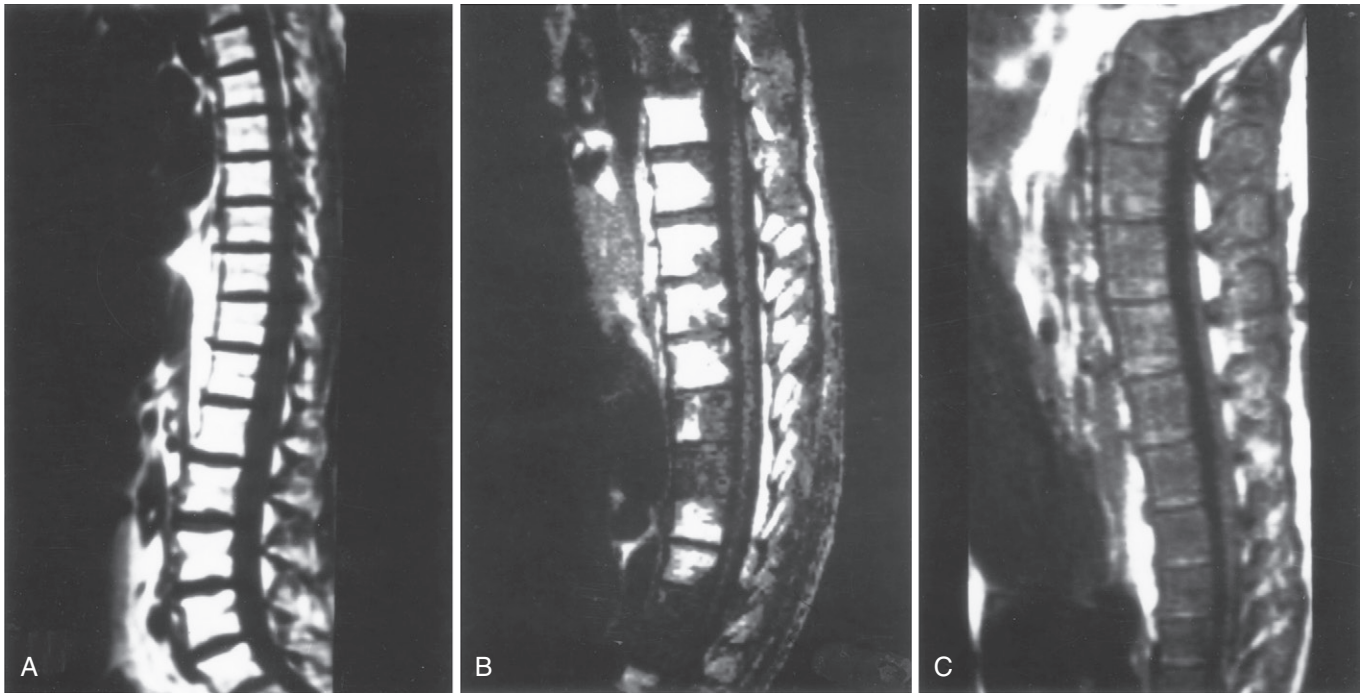

Figure 28-10 MAGNETIC RESONANCE IMAGING OF BONE MARROW. **A,** Bone marrow in a young man with severe aplastic anemia, a middle-aged woman with severe aplastic anemia **(B)**, and a middle-aged woman with myelodysplasia **(C)**.

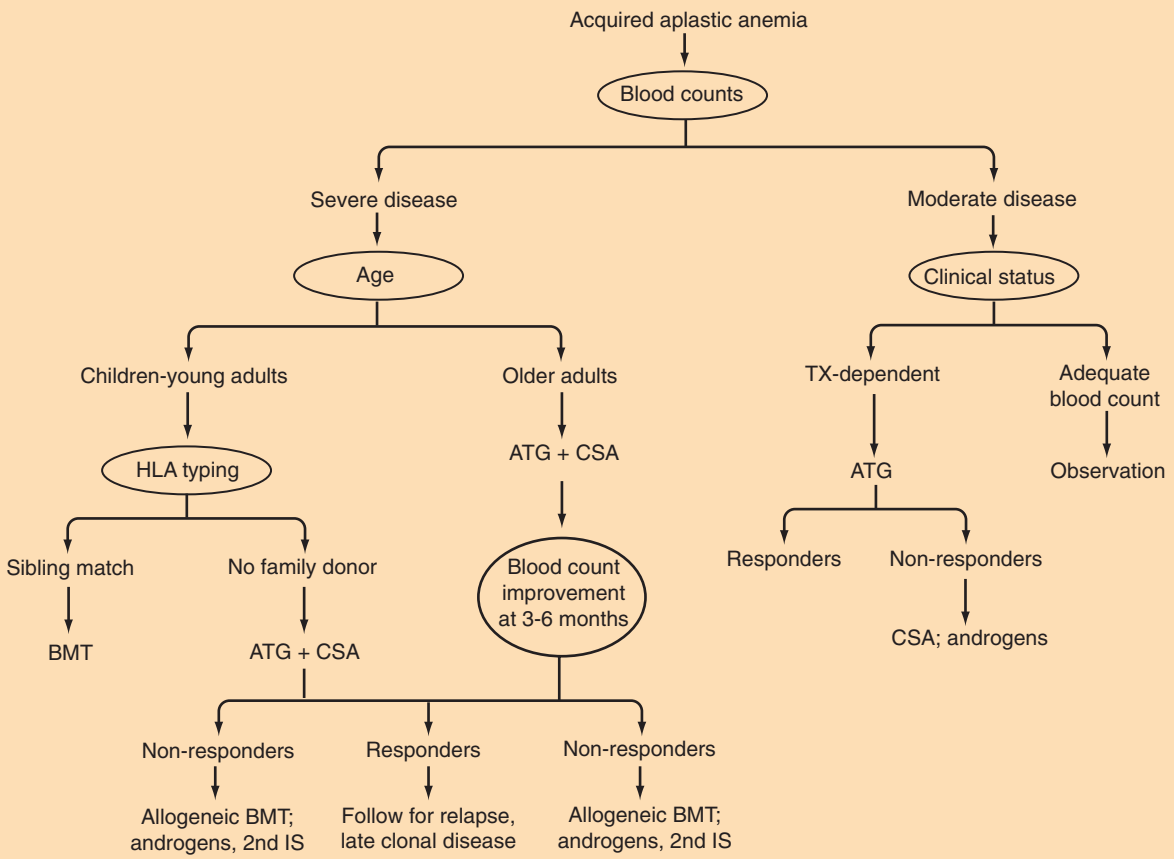
patient succumbs to an early clinical catastrophe. A haphazard transfusion policy increases the risk of graft rejection after BMT, but an overly conservative approach to transfusion can jeopardize the patient's life and increase morbidity. Supportive management therefore requires meticulous attention to the daily problems that occur as a consequence of pancytopenia and appreciation of their impact on the ultimate possibilities for cure or amelioration of AA. AA can be cured by replacement of stem cells, by BMT, and by immunosuppressive therapy. Androgens and hematopoietic growth factors have secondary roles (see box on Treatment Algorithm in Aplastic Anemia).

Supportive Management



Bleeding

Bleeding was historically a common symptom in AA, and death from hemorrhage occurred frequently in the premodern era. Platelet transfusions have substantially improved survival in patients with this disease. Measurable correction of the platelet count by transfusion almost always alleviates the minor mucocutaneous bleeding common in thrombocytopenic patients. Major bleeding usually is not caused by thrombocytopenia alone, and ancillary explanations for massive hemorrhage should be sought. The bleeding time improves after erythrocyte transfusion in patients with anemia, and there is a strong inverse correlation between the hematocrit and bleeding. The treatment of serious hemorrhage should include correction of severe anemia and RBC transfusions.

Modern transfusion practice has made platelets readily available and safe to administer. Other than cost and convenience, the major problem related to platelet transfusions is the development of alloimmunization in the recipient. The life span of the transfused platelet in the circulation is dramatically shortened by host antibodies, almost always directed to HLA-A and HLA-B antigens. Alloimmunization is suggested by poor recovery of the 1-hour posttransfusion platelet count and confirmed by finding specific HLA antibodies in serum. Refractoriness can often be overcome by selection of HLA-matched donors, but perfectly HLA-matched transfusions can fail. Alloimmunization can be prevented or delayed by the use of single-donor platelets rather than pooled platelets and by physical leukocyte depletion by filtration or ultraviolet treatment of blood products. Avoidance of platelet transfusions except when there is active bleeding is another alternative to prevent alloimmunization, but the dose relationship between exposure to different donors' platelets and the probability of developing refractoriness is not clearly established, and only after more than about 40 units have been administered does the risk of alloimmunization clearly increase.

Prophylactic transfusion of platelets is not standard. The primary indication for platelet prophylaxis is to prevent intracranial hemorrhage, but the risk of this complication in chronically thrombocytopenic patients, although real, is low. Prophylactic platelet transfusions have not been shown to alter survival. Nevertheless, the beneficial effects of avoiding bleeding complications and improving the quality of life justifies their use. Although the 20,000 platelets/μL value has long been used to trigger transfusion, many reports have suggested little difference in the risk of bleeding over a wide range of platelet counts between 5000 and 100,000 platelets/μL. In a randomized trial

Treatment Algorithm in Aplastic Anemia

Algorithm-based selection of treatment for patients with aplastic anemia. *ATG,* Antithymocyte globulin; *BMT,* bone marrow transplantation; *CSA,* cyclosporine A; *HLA,* human leukocyte antigen; *IS,* immunosuppression; *TX,* treatment.

of patients with AML, the risk of major bleeding was no different when 10,000 or 20,000 platelets/μL was chosen as the threshold, but the lower value led to a 20% reduction in platelet use. Any prophylaxis program must be modified to address the individual patient, but a goal of maintaining platelet counts higher than 10,000 platelets/μL is reasonable.

Major surgery can be accomplished in the setting of thrombocytopenia. In one study, blood loss and morbidity rates were low even at platelet counts of less than 30,000 platelets/μL.

Anemia

Other than to reduce the risk of graft rejection after receiving an allogeneic transplant, there is no reason to allow a patient to suffer the symptoms of anemia. After equilibrium is achieved, a constant amount of blood will be required to maintain a given hemoglobin concentration. Physically fit individuals are usually not symptomatic at hemoglobin concentrations higher than 7 g/dL; patients with underlying cardiovascular disease should be maintained at a higher level (≥9 g/dL). Iron chelation should be used in patients with unresponsive chronic anemia who have a reasonable expectation of survival.

Alloimmunization as a result of blood product administration increases the probability of graft rejection and mortality after BMT. Blood products from a potential BM donor such as a sibling or a parent (who share histocompatibility antigens) should be avoided. Small numbers of transfusions do not have a major deleterious effect on survival. The 5% risk of graft rejection after transplantation in entirely untransfused patients was increased to 15% with receipt of 1 to 40 units and to higher than 25% only in more heavily transfused patients. Graft rejection would be anticipated to be lower with leucocyte-depletion methods of platelet preparations. Speed in arranging tissue typing and transfer to an appropriate center has a greater impact on the survival of the patient than the judicious transfusion of a few units of RBCs to a severely anemic patient or platelets to a bleeding patient. Transfusions should not be withheld in an older patient in whom immunosuppressive therapy will be the first-line therapy.

Infection

There are very few specific reports of infections and their therapy in patients with AA. The duration of neutropenia is the major difference between the neutropenia of BM failure and that induced by cytotoxic chemotherapy. With longer periods of neutropenia, the probability of serious bacterial or fungal infection increases. A second major difference is that neutropenia is part of a complex of problems associated with malignant disease and its therapy. In AA, the immune system is activated, and with the exception of intravenous catheter placement, the integument is preserved. Studies of cancer patients have usually identified a low-risk category of neutropenia, determined by the relatively brief period of neutropenia; by this criterion, almost all unresponsive patients with AA are at high risk.

In classic studies of children with leukemia, neutropenia was shown to increase susceptibility to bacterial infections, and the number of infectious episodes correlated with the degree and duration of neutropenia. Susceptibility to infection is extremely high with an absolute neutrophil count (ANC) of less than 200 platelets/μL, and this value has been used to define a category of very severe AA. As severe granulocytopenia becomes prolonged, infection is inevitable. Recommendations for initiation of empirical antibiotic therapy are similar for AA patients and other patients with neutropenia. The cardinal rule is, if the ANC is less than 500 cells/μL and infection is suspected, broad-spectrum parenteral antibiotic therapy should begin immediately. Any regimen can need modification based on results of cultures, new symptoms or signs, or a deteriorating clinical course. Bacteremia is present in only 20% of febrile neutropenic episodes, and in only approximately 40% of those can a microbiologic cause or localizing physical findings be identified. Early discontinuation of antibiotics when cultures are unrevealing in persistently neutropenic patients is dangerous.

Patients often remain febrile despite antibiotic therapy or fever reappears. In the absence of additional microbiologic data or clinical clues from the patient's complaints or physical examination, antifungal therapy should be instituted in patients who have remained febrile despite adequate antibacterial therapy. Earlier addition of anti-fungal drugs is advisable in AA patients, especially if there are findings on chest tomography and a positive test result for galactomannan protein. Fungemia during an initial febrile episode is rare, but fungal infection becomes more likely with repeated courses of antibiotics and ultimately is the major cause of death in AA patients in whom definitive therapy fails. *Candida* and *Aspergillus* spp. account for almost all fungal diseases in AA. Early aggressive treatment of neutropenic patients can reverse fungal disease. Large randomized trials have shown that newer antifungal agents such as voriconazole and caspofungin are less toxic and as effective or superior compared with amphotericin and liposomal amphotericin for the treatment of both persistent neutropenic fever and established *Candida* and *Aspergillus* infection. Improved survival in severe AA is caused in some part by better antifungal drug therapies.[14]

Polymorphonuclear cells have a relatively brief life span in the circulation, and their major activity is in infected tissue. There are no simple measures of the therapeutic efficacy of WBC transfusions. The ANC is not measurably increased by standard transfusions. Several controlled trials performed in the 1970s reported improved survival in patients who received granulocyte transfusions; negative studies may have used relatively low numbers of granulocytes transfused ($<10^{10}/m^2$/day). Granulocyte transfusions are expensive and associated with serious toxicity, including severe febrile reactions, pulmonary capillary leak syndrome, an increased risk of infection, and inevitable alloimmunization. Cytokines offer a strategy for increasing the efficiency of donor harvests. Administration of G-CSF to normal donors greatly increases the yield of leukapheresis without adverse effects on the volunteers. Excellent results can be obtained from community donors, and the use of allocompatible granulocytes (as determined by lymphocytoxicity screening assay) can further improve the clinical results of granulocyte transfusions. Large numbers of neutrophils can be obtained, allowing dramatic increases in the absolute granulocyte levels in neutropenic recipients, which can improve clinical outcomes; case reports and phase I and II studies have suggested that G-CSF (G-CSF plus dexamethasone)–mobilized granulocyte transfusions can be helpful in the treatment of life-threatening fungal infections in severely neutropenic patients.[15]

Definitive Therapy

Hematopoietic Stem Cell Transplantation

Allogeneic BMT from an HLA-matched sibling donor provides curative therapy for AA patients (Tables 28-8 and 28-9).[16]

Bone marrow transplantation in AA is the subject of a large number of reports and reviews. Cytokine-mobilized peripheral blood also has been used successfully as a stem cell graft, but recent studies suggested that mobilized peripheral blood stem cell grafts are associated with a worse outcome.[17]

The first studies of allogeneic BMTs conclusively demonstrated their value compared with conventional supportive therapy. In a controlled trial reported by the International Aplastic Anemia Study Group, patients with severe disease who received transplants early had an actuarial survival rate of more than 60% compared with approximately 20% in patients who received androgens and blood transfusions only. Results with BMT have improved over time because of a combination of factors, including progressive modification of conditioning regimens and lower procedure-related early mortality, improved transfusion support and antibiotic regimens, and the introduction of cyclosporine as prophylactic therapy for GVHD. Analysis of the International Bone Marrow Transplant Registry data showed

EBMT, European Group for Bone Marrow Transplant; *GVHD,* graft-versus-host disease; *IBMTR;* International Blood and Marrow Transplant Registry.
GVHD results are generally for grades II–IV and in patient at risk.
Only studies reporting ≥20 patients are tabulated.
In contrast to Table 28-1, response rates are not provided because, in surviving patients who do not experience primary graft rejection or secondary graft failure, full hematologic recovery with donor hematopoiesis is anticipated.

that 5-year survival rates climbed from 48% in the years 1976 to 1980 to 66% in 1988 to 1992. Some hospitals now report very high rates of survival: 89% in Seattle at 8 years, 79% in Baltimore, 89% and 95% at Viennese centers. Registry data indicate lower survival values as the general experience for the same period, with 64% of patients who received transplants during the period of 1985 to 1991 alive at 5 years after the procedure. Between 1990 and 1994, the European Group for Bone Marrow Transplantation (EGBMT) reported a 72% survival rate at 3.5 years. In the latest updates of the EGBMT, the long-term survival had further improved over the past 5 years to 80%.[18]

In the most favorable subgroup—untransfused or minimally transfused young, uninfected patients—survival rates of 80% to 90% should be routinely achieved (see Fig. 28-10). Overall, the survival rates reported from major centers are approximately 70%.

Therapy for Aplastic Anemia

After the diagnosis of acquired AA has been established, treatment options must be identified, considered carefully, and chosen with alacrity (see box on Treatment Algorithm in Aplastic Anemia). For patients with moderate disease (see Table 28-6), an expectant approach can be chosen based on a stable course and adequate blood counts, or for patients dependent on transfusion support, horse ATG (40 mg/kg/day for 4 days) can be given. Intradermal sensitivity testing with 50 ng/mL of ATG solution should be performed, and patients showing an immediate reaction should be desensitized. After assessment of the response, patients who improve should be monitored for hematologic signs of relapse and nonresponders can be offered alternative therapy, such as androgens or cyclosporine. In severe disease for which the prognosis with blood transfusion and antibiotic support alone is very poor, BMT from a histocompatible sibling or immunosuppression are accepted and effective therapies. Although large, retrospective analyses have shown that long-term survival rates from transplantation or immune therapy are equivalent, each has its own advantages and disadvantages. For children, BMT remains the treatment of choice if an appropriate family donor is available because these patients have a low rate of GVHD, and the BM disease is cured by stem cell replacement. The risk of therapy-related cancers can be increased, especially in children, after BMT. Adults with AA also successfully receive transplants, although the risk and severity of chronic GVHD and other treatment-related complications increase with age. BMT has been performed in patients older than 50 years of age, and it is a reasonable approach in a younger adult, especially with more severe degrees of neutropenia.

Most patients with AA do not have an HLA-matched sibling donor, and immunosuppression is the treatment of choice in these cases. Patients with severe disease should receive a combination of ATG and cyclosporine. The authors recommend a regimen consisting of 40 mg/kg/day of horse ATG on days 1 to 4 followed by cyclosporine for 6 months at a dose of 12 mg/kg. Corticosteroids are added in moderate doses (1 mg/kg of prednisone or methylprednisolone) during the first 2 weeks to ameliorate serum sickness. Improvement should be expected within 6 months. This regimen has produced hematologic responses in approximately 70% of treated patients, who then have an excellent 5-year survival rate.

Although immunosuppressive therapy is relatively nontoxic, patients frequently relapse and require further treatment; however, relapse is not associated with a poor prognosis. A more serious problem is the development of late-onset hematologic clonal diseases, PNH (which may not be clinically significant); MDS; and rarely, acute myeloid leukemia. Immunosuppression can be considered ameliorative therapy in which BM destruction may continue and abnormal stem cell clones develop.

For patients in whom immunosuppressive therapy fails, there are a number of options. For children, alternative donor BMT should be seriously considered; at the best centers, survival rates now are almost as good as with sibling donors. Adults do less well, primarily because of transplant-related mortality from the intensive conditioning regimen. Some patients respond to androgen therapy and others to combinations of growth factors. Repeated immunosuppression in a

patient in whom a first course of ATG and cyclosporine has failed is successful in about 30% of cases. High-dose cyclophosphamide can also be effective therapy for AA at presentation and in patients who are refractory to ATG.

Patients with severe AA should not be subjected to useless early trials of corticosteroids or hematopoietic growth factors as the primary treatment. For the occasional patient who must decide between BMT and immunosuppression, the advice of experts familiar with this disease and careful counseling of the patient are advisable. Age and severity of neutropenia are decisive factors. A limited number of transfusions can be necessary to optimize the patient's condition before definitive therapy and are acceptable. Single-donor platelets should be given and can be obtained from HLA-compatible donors. In severely neutropenic patients, G-CSF therapy can decrease the risk of life-threatening infections.

Graft rejection and GVHD are the major complications of allogeneic transplantation in AA. Graft rejection is a major predictor of posttransplantation survival. The rate of graft rejection decreased with intensification of the immunosuppressive conditioning regimen from 15% to 4% in Europe and from 35% to between 10% and 15% in Seattle and has remained stable in the past decade. Graft rejection can be caused by the pathophysiology of AA, a finding supported by the unexpectedly high proportion of failures in unprepared patients receiving syngeneic transplants and even in adequately preconditioned patients receiving syngeneic transplants. In a group of untransfused patients who received allogeneic stem cells, the incidence of graft rejection was 10%, indicating that AA patients may be particularly sensitive to alloimmunization. Nevertheless, the influence of the number of transfusions on graft rejection is relative, and modest numbers of blood donations (40 units in the International Bone Marrow Transplant Registry experience and less than 10 units of erythrocytes or 40 units of platelets in Seattle) did not greatly increase the risk of graft rejection.[19]

Matched Sibling Donor (Hematopoietic Stem Cell Transplantation [see Table 28-8])

Intensification of immunosuppressive conditioning regimens with the use of total-body or lymphoid irradiation, cyclosporine, or ATG reduces the risk of graft rejection. Such measures, however, have not been shown to influence long-term survival.[16] The effect of the conditioning program on graft rejection probably is achieved through elimination of the recipient's lymphocytes and of subsequent mixed hematologic chimerism, which is associated with rejection. More rapid regeneration of BM grafts has been observed when cyclosporine was used, and second transplantations have been successful when ATG was added to the conditioning regimen. The effect of ATG or cyclosporine in the conditioning regimen on the rate of graft rejection has been tested in randomized studies. Conditioning regimens that do not include irradiation now regularly achieve engraftment and avoid many of irradiation's long-term complications, especially late cancers. In patients who were prepared by cyclophosphamide plus ATG, sustained engraftment can be achieved by more than 90%, and patients who reject the graft can still be successfully retransplanted. The combination of cyclophosphamide plus fludarabine, with or without ATG, has achieved high rates of graft acceptance and survival even in heavily transfused patients who are transplanted with mobilized peripheral blood stem cells, months after proving refractory to immunosuppressive drugs. The use of methotrexate and cyclosporine has not improved rates of GVHD compared with cyclosporine, but surprisingly, methotrexate was associated with a better survival rate for patients with AA transplanted from matched sibling donors.[20] Overall, the reported rejection rates range between 10% and 15%, account for 14% of deaths in the first 100 days after transplantation and 23% of deaths thereafter.

Rates of chronic GVHD vary and are related to patient selection and treatment regimens. Historically, age was the major risk factor for the development of chronic GVHD. The incidence of chronic GVHD ranged from 19% to 90% for patients between 0 and 10 years and older than 31 years in an older Seattle series. With improved treatment regimens, patients have fared better, but additional studies have confirmed a higher incidence and more serious consequences of GVHD in older patients. Children have a lower probability of suffering and dying from chronic GVHD. In an EGBMT analysis, a significant survival difference was observed between those younger than 20 years of age (65%) and those older than 20 years of age (56%), but there was no survival difference between patients 21 to 30 years old and those 31 to 55 years old. Young adults have fared better in other series, although morbidity from severe GVHD disease was far more prevalent in the young adults than in children (43% vs. 10%). Overall, the acute GVHD rate between 1991 and 1997 was approximately 20% for patients younger than 20 years of age and 40% for those older than 40 years of age. In general, similar numbers were cited for chronic GVHD.[16]

In summary, excellent survival rates and low morbidity in younger patients make allogeneic BMT the treatment of choice for children and adolescents. Older adults have a higher risk of transplant-related morbidity and mortality. Younger adults have a good opportunity for cure with transplantation but face more complications than children. In addition to age, a prolonged interval between diagnosis and transplantation, multiple transfusions, and serious infections before transplantation are poor risk factors.

Matched Unrelated and Nonhistocompatible Family Donors (see Table 28-9)

Until recently, the lack of an HLA genotypically identical sibling donor has precluded BMT, excluding approximately 70% of patients with AA from access to this therapeutic option. Alternative potential donors include relatives who are phenotypically matched or partially matched and HLA phenotypically matched but unrelated volunteers. Although phenotypically identical family donors are occasionally available, mismatched family members and matched but unrelated donors represent a much larger pool.

Haplotype sharing between parents occasionally has allowed identification and successful transplantation between phenotypically matched relatives. Long-term survival after even one-locus-mismatched family donation is inferior to genotypically matched transplants, mainly because of graft rejection and GVHD. In the large European experience, for phenotypically identical family matches, the actuarial survival rate was 45%; for patients with a single-locus mismatch, it was 25%; and for those with two to three loci mismatched, the survival rate was 11%. In a report from Seattle, although all patients who received fully HLA-matched transplants survived, those with mismatches at one or more loci had a much poorer outcome, and even with total-body irradiation added to the conditioning regimen, the survival rate was only 50%. Most large studies of unrelated donors have shown inferior long-term survival and higher rates of complications such as graft rejection, GVHD, and delayed immune system reconstitution. Even more than in standard sibling transplants, age is a crucial risk factor in unrelated transplants and probably more important than the level of match, conditioning regimen, or use of T-cell depletion. For patients with AA who received unrelated transplants and who were enrolled in the National Marrow Donor Program, the survival rate at 2 years was 29%. In the EGBMT's 1994 report, the survival rate for 110 recipients of BM grafts from other than a matched sibling was 34%, approximately half of the rate of standard transplantation. Superior results were obtained at Children's Hospital in Milwaukee, where T-cell depletion of the donor graft was combined with a rigorous conditioning program of cytosine arabinoside, cyclophosphamide, and TBI. For 28 transfused and previously treated children with severe AA, a survival of 54% was reported at a median follow-up of almost 3 years, with no incidence of chronic GVHD. Similar results have been reported in a series of 154 transplantations performed in patients between the ages of 1 and 46 years of age (median, 17 years of age), with delayed transplantation (>3 years after diagnosis), HLA-A or HLA-B mismatch, and age being poor risk factors. In a meta-analysis, for fully matched,

unrelated recipients, the survival rate was 25% to 50%, with rates of graft failure and GVHD of 0% to 50% and 28% to 100%, respectively. The degree of match clearly impacts the outcome of the unrelated BMT. As shown in the recent study with mismatched related and unrelated transplantation, the survival was highly related upon degree of mismatch with survivals of 49%, 30%, 39%, and 36% for after 1-antigen mismatched related donor, more than 1-antigen mismatched related donor, matched unrelated donor and mismatched unrelated donor transplants, respectively.[21]

Retrospective analysis of 71 AA patients treated with umbilical cord transplantation showed the estimated probability of 3-year overall survival of 38% (median follow-up, 35 months); the cell dose appeared to be the most important factor impacting survival.[22]

Despite progress, matched but unrelated transplantation is associated with a high mortality rate, and perhaps refractory, high-risk patients are therefore often selected for this procedure. It is likely the poor results may be a consequence of this referral bias. However, alternative-donor transplantation is feasible; the rare phenotypic match from within the family may be equivalent to a sibling donor, but with other family members or unrelated donors, there is a high risk of transplantation-related mortality. Because unrelated-donor transplantation takes months to arrange, it should be considered early. At the best centers, alternative-donor transplantation represents an option, especially for the young patient with very severe pancytopenia in whom immunosuppressive therapy has failed. In Japan, an unrelated but matched transplant has been reported to produce better results in refractory pediatric cases when used early rather than after repeated courses of immunosuppression. In an analysis from Seattle, patients who failed one or more courses of immunosuppression had an overall survival rate of 36% at 3 years.

Late Complications of Bone Marrow Transplantation

Recent study analyzing outcomes of children with AA over the 4 decades indicates that the majority of long-term survivors after transplantation during childhood can have normal, productive lives, with a 30-year survival rate of 82%.[23]

Very late complications after transplantation include effects on growth and development, as well as on the function of endocrine, neurologic, and other organ systems. A high rate of secondary malignancies has been recorded after transplantation. In a National Cancer Institute retrospective analysis of almost 20,000 transplantations, the risk of late-onset cancer was eightfold higher at 10 years than in the general population and even higher for young patients, for whom the risk of malignancy was increased approximately 40-fold. Multivariate analysis suggested that high-dose radiation was a risk factor for the development of malignancies. For AA, among 320 patients who received transplants in Seattle, 4 developed cancer, leading to a calculated risk seven times higher than for normal control participants. In a recent update, 12% of patients who survived more than 2 years after transplantation developed solid tumors. In a French survey, 4 of 147 AA patients developed solid tumors, an 8-year cumulative incidence rate of 22%. In an analysis of 700 transplantation patients with AA and FA, the risk of developing a secondary malignancy was 14% at 20 years. The hazard of lymphoid malignancies decreased with the time after transplantation, but the risk of solid tumors progressively increased. Secondary solid cancers developed in the radiation fields of 5 of 147 AA patients whose conditioning regimens included irradiation of the thorax and abdomen. In general, the rates of secondary malignancies after BMT for AA and other diseases are similar. Immune events such as acute GVHD, treatment with ATG or monoclonal antibodies, and irradiation have been related to the development of secondary malignancies. Patients with these secondary cancers have a poor prognosis. The risk of cancer after BMT must be evaluated in the context of other therapeutic options, especially immunosuppression, because a significant risk of late malignancy exists in AA patients independent of transplantation therapy. The risk of malignancy in the large registry of the EGBMT was equivalent for patients who received immunosuppression and those who underwent transplantation. Compared with the general European population, the relative risk of malignancy was calculated at 5.15 for AA patients treated with immunosuppression (confidence interval [CI], 3.26-7.94) and at 6.67 (CI, 3.05-12.65) for patients receiving transplants. Overall, the rate of malignancy after BMT has been calculated to be 3.8-fold higher than in the age-matched population.

Immunosuppression

Antithymocyte Globulins

Immunosuppressive therapy is an effective alternative treatment for patients who are not candidates for BMT (Table 28-10 and see box on Treatment Algorithm in Aplastic Anemia).[2]

Immunoglobulin preparations made from the sera of horses immunized against human thymocytes are the mainstays of current regimens. Horse ATG is licensed for use in the United States as ATGAM (Pfizer) and SAA is an approved indication. Thymoglobulin (Genzyme), a rabbit ATG, is more available worldwide.

The efficacy of antilymphocyte globulin (ALG) in BM failure was discovered serendipitously in the late 1960s, when Mathé observed recovery of autologous hematopoietic function in patients who received antilymphocyte serum as conditioning for BMT. Observations and formal studies in Europe showed that 40% to 70% of patients responded with hematologic improvement and improved survival. Similar results were also obtained in American randomized and multicenter protocols in which about half of patients treated with ATG or ALG show hematologic improvement, broadly defined as an end to transfusion dependence and an improvement in a neutrophil number to a level protective against infection.

Table 28-10 Intensive Immunosuppression in Severe Aplastic Anemia

Study	Patients *(n)*	Median Age (Years)	Response (%)	Relapse (%)	Clonal Evolution (%)	Survival Rate
German	84	32	65	19	8	58% at 11 years

NIH	122	35	61	35	11	55% at 7 years
Japan*	119	9	68	22	6	88% at 3 years
NIH†	104	30	62	37	9	80% at 4 years

*With androgens and ± granulocyte colony-stimulating factor.
†With mycophenolate mofetil.
Only studies of more than 20 enrolled patients are tabulated. Responses to immunosuppressive therapy are usually partial; blood counts may not become normal, but transfusions are no longer required, and the neutrophil count is adequate to prevent infection. Relapse is usually responsive to further immunosuppressive therapies. Clonal evolution is to dysplastic bone marrow changes or cytogenetic abnormalities. For details, see accompanying text.

The putative cause of AA is not a factor that predicts response. Virus- and drug-induced aplasia and posthepatitis AA respond similarly compared with idiopathic disease. Cytogenetic abnormalities do not preclude a response because AA with chromosome abnormalities and some cases of frank myelodysplasia improve after ATG. The response rate to ATG or ALG is not improved by the addition of androgens or very high doses of corticosteroids.

A hematologic response to ATG is usually apparent within a few months of therapy; in some cases, all blood counts rise dramatically, but in others, increases in platelets or RBCs can be delayed (see box on Treatment Algorithm in Aplastic Anemia). The average time to improvement in neutrophil number is 1 to 2 months; transfusion independence occurs approximately 2 to 3 months after initiation of treatment. Continued improvement without further therapy commonly occurs after 3 months; nevertheless, clinical status by 3 months is strongly correlated with long-term survival. Blood cell counts above the critical values for severity and platelets and reticulocyte counts of more than 50,000 cells/μL are highly prognostic. Patient selection is important; in general, survival correlates with disease severity. However, in most recent series, reticulocyte count, perhaps reflecting the stem cell reserve, has been the best predictor of response and survival.[24] With new and better tolerated antifungal drugs, survival even of nonresponders has improved, and a very low neutrophil count may no longer have prognostic value.

Antithymocyte globulin has three major toxic effects: immediate allergic phenomena, serum sickness, and transient blood cell count depression (Fig. 28-11). Fever, rigors, and an urticarial cutaneous eruption are common on the first or second day of ATG therapy, and these symptoms respond to antihistamines and meperidine therapy. Anaphylaxis is rare but can be fatal. A positive immediate wheal-and-flare reaction to the cutaneous application of 50 mg/mL of stock solution of horse ATG can be predictive of massive histamine release on systemic infusion, and desensitization with gradually increasing doses of horse ATG administered intradermally, subcutaneously, and then intravenously has permitted use in allergic individuals. Corticosteroids are administered in moderate doses (1 mg/kg of prednisone or methylprednisolone) during the first 2 weeks to ameliorate the symptoms of serum sickness. Doses of ATG and ALG have varied from 5 to 50 mg/kg, and the duration of administration has varied from 4 to 28 days. It is more rational to administer equivalent doses of horse ATG by the schedule originally used in Europe (40 mg/kg/day for 4 days); antiserum will then have reached low levels in the circulation by the time host antibody appears. A short course of therapy is easier to administer, associated with less serum sickness, and equally effective as the same dose given over a more prolonged course. Thymoglobulin, rabbit ATG, has been approved for use in the United States. Although rabbit ATG is more potent by weight than horse ATG, a recent randomized trial showed it markedly inferior to horse ATG in achieving hematologic response, and survival was poorer as well.[25]

Antilymphocyte globulins are immunosuppressive. ATGs contain a heterogeneous mix of antibody specificities for lymphocytes, including reactivity to antigens such as CD2, CD3, CD4, CD8, CD25 (the receptor for IL-2), and HLA-DR. Horse sera fix human complement efficiently, and all preparations are T-cell cytotoxic in vitro, with little difference among ATGs or among lots for lymphocyte killing in vitro. In vitro, ALGs efficiently inhibit T-cell proliferation and block IL-2 and IFN-γ production, and IL-2 receptor expression ATG induces Fas-mediated apoptosis of T cells, especially after activation. In patients, the administration of ATG results in rapid reduction in the number of circulating lymphocytes, usually to less than 10% of starting values, and lymphocytopenia persists for several days after discontinuing therapy. Although lymphocyte numbers return to pretreatment values by 3 months, reductions in activated lymphocyte numbers in recovered patients persist. It seems likely that these inhibitory effects on T cells are responsible for the efficacy of ALGs in AA. Nevertheless, the ability of ATG to stimulate lymphocyte function by acting as a mitogen may also have a role in their therapeutic efficacy. Notably, rabbit ATG can stimulate regulatory T cell development in vitro and in patients, although this effect in AA is overwhelmed by rabbit ATG's more potent CD4 cell depletion compared with horse ATG.

Reliable methods to predict which patients will respond to ATG are lacking.

Cyclosporine

Several groups reported anecdotal success with cyclosporine therapy combined with androgens in individual patients with AA, in many of whom other therapies had failed. Some studies suggested efficacy of cyclosporine in patients refractory to ALG or ATG alone, with salvage rates of approximately 50%. The optimal regimen has not been determined. In the United States, cyclosporine has usually been used in high doses (12 mg/kg/day for adults and 15 mg/kg/day for children), with adjustment according to plasma drug concentrations and serum creatinine levels. In Europe, lower doses (3-7 mg/kg/day) have been reported to be equally efficacious. Hematologic improvement can occur in a few weeks or months. A 6-month trial is warranted. Remissions, when achieved, usually have been durable, but some patients relapse when cyclosporine is discontinued. Most patients who relapse will respond to the reinstitution of cyclosporine; the lowest possible dose should be sought by tapering, but some patients may require long-term maintenance treatment.

Cyclosporine has considerable toxicity. Hypertension and azotemia are the most common serious side effects; hirsutism and gingival hypertrophy are also frequent complaints. Increasing serum creatinine levels are an indication for dose reduction. Chronic cyclosporine nephropathy characterized by interstitial fibrosis and tubular atrophy can be irreversible. The risk of nephropathy is increased by high doses and longer durations of therapy and occurs more commonly in older than in younger patients. Cyclosporine, especially in combination with corticosteroids, converts patients with AA to a temporary immunodeficiency state and puts them at high risks for opportunistic infections. Monthly aerosolized pentamidine prophylaxis can prevent *Pneumocystis carinii* pneumonia in patients receiving cyclosporine. Convulsions, possibly related to hypomagnesemia, are another serious complication of cyclosporine therapy.

Combined or Intensive Immunosuppressive Therapy

The combination for the treatment of AA of an agent that lyses lymphocytes (ATG) with a drug that blocks lymphocyte function is

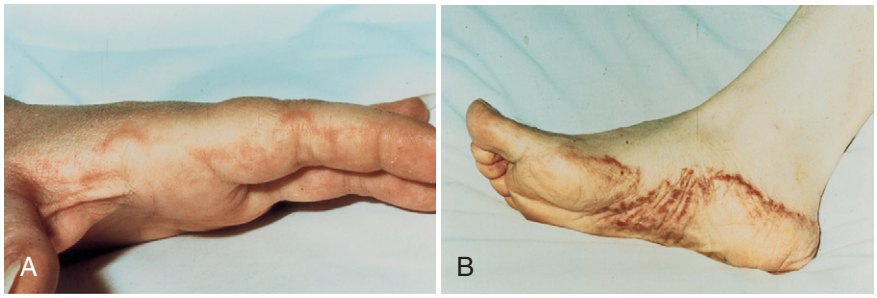

Figure 28-11 CUTANEOUS ERUPTIONS OF SERUM SICKNESS. On the hand **(A)** and on the foot **(B)**.

rational (see Table 28-10). The strategy has resulted in a striking increase in the response rate to immunosuppressive therapy in randomized and multicenter trials, to 60% to 80% at 1 year compared with about 40% with ATG alone; more complete response;, and better 5-year survival rates for responding patients at 80% to 90%. Children do especially well with combined therapy, elderly patients less so, partly because of more toxicity from therapy and poor tolerance of pancytopenia complications in the presence of comorbidities.

In disease refractory to initial therapy with ATG and cyclosporine, a repeat course is often administered as a salvage regimen and can rescue about one-third or more of patients.

Cyclophosphamide

High-dose cyclophosphamide (45-50 mg/kg/day for 4 days) without stem cell rescue can induce hematologic recovery in severe AA, with an overall response rate claimed similar to that achieved with ATG therapy but a higher proportion of complete responses and less relapse and clonal evolution. However, cyclophosphamide severely depresses the neutrophil count, resulting in prolonged hospitalization for suspected or actual infection and a higher risk of invasive fungal infections and death compared with ATG and cyclosporine.

Corticosteroids

Methylprednisolone in modest doses (1 mg/kg/day) is administered with ATG to ameliorate the symptoms of serum sickness. Very-high-dose corticosteroid regimens can be effective, especially in recently diagnosed patients. High-dose methylprednisolone also has been added to ATG therapy, with inconsistent results. However, ATG is associated with better response rates and many fewer associated toxic effects than high-dose steroid therapy, and ATG is generally preferable as initial therapy. Modest doses of corticosteroids do not have roles in the treatment of AA except in combination with ATG. There is little evidence of their effectiveness in reversing BM failure or improving hemostasis, and even limited courses of steroids can contribute to the development of aseptic vascular necrosis and the increase in the rate of fungal infections.

Late Complications of Immunosuppressive Therapy

Relapse after immunosuppressive therapy is common. About one-third or more of responding patients may be expected to require reinstitution of immunosuppressive drugs or another course of ATG. Relapse can manifest as a gradual decline in one blood count, need for transfusion after a period of transfusion independence, or abrupt recurrence of severe pancytopenia. Most relapse responds to retreatment, and there is no clear relationship with worse survival.

A much more serious complication is the development of late-onset clonal hematologic disorders, especially myelodysplasia and AML. Some of these events likely represent part of the natural history of AA. Before recent improvements in treatment, leukemia was considered an unusual complication, but late-onset clonal disorders do not appear to be the result of the introduction of immunosuppressive therapy. In European and National Institutes of Health trials, the overall rate of clonal evolution is 12% to 15% at about 1 decade. Children appear to be at similar risk for the development of clonal complication as adults, and evolution to MDS can occur in responders and in refractory patients. MDS that develops after AA can progress to AML but can also be surprisingly indolent. BM chromosomes are almost always abnormal in clonal evolution, and cytogenetics are predictive. Monosomy 7 is the most frequent finding and confers a poor prognosis; in contrast, patients with trisomy 8 patients often remain responsive to cyclosporine and have good prospects for survival. Trisomy 6 and 13q− also behave benignly in most cases.

A PNH clone can be detected in up to 50% of patients on their presentation. Usually the clone size remains stable, and it may decrease; over time, only a minority of patients develop a large clone and the hemolytic or thrombotic form of PNH.

Immunosuppression Versus Bone Marrow Transplantation

Immunosuppression and transplantation are both effective therapies for AA[2] (Figs. 28-12 and 28-13). Lack of a matched sibling donor; the expense and availability of transplantation; and risk factors such as active infections, advanced age, or a heavy transfusion burden lead most patients to treatment with ATG and cyclosporine. For a few patients with AA, a choice does exist between transplantation and immunosuppressive therapy. BMT offers a permanent cure. Its disadvantages are cost, procedure-related morbidity and mortality (especially GVHD in older patients), and an increased incidence of solid organ malignancies. Immunosuppressive therapy is easier and initially cheaper. However, many patients do not achieve normal blood cell counts and remain at high risk for relapse and the more serious complications of late-onset clonal hematologic disease, especially MDS.

Retrospective analyses of the large number of European patients reported to the EGBMT show consistently improved results with both therapies but have repeatedly failed to demonstrate a survival advantage for transplantation over immunosuppression. Single-center studies are similar. Certain categories of patients, defined by neutrophil number and age, probably benefit from one therapy or the other. In general, BMT yields superior results in children and immunosuppression in older adults.[16]

Remarkable improvements in results using unrelated donors have made this transplant available to many patients who lack a sibling donor. Increasingly, children who have failed a single course of immunosuppression and adults refractory to multiple courses of ATG are offered this procedure.

Androgens

Testosterone and synthetic anabolic steroids appeared to be major advances in the treatment of AA when they were introduced in the 1960s. The high response rates in some early series may be retrospectively attributed to the inclusion of patients with moderate acquired and constitutional AA. For severe AA, controlled trials in general have not demonstrated efficacy, as measured by survival rates or hematologic improvement. When added to immunosuppressive therapies, androgens failed to result in any increase in response rates.

Although BMT or immunosuppressive therapy is generally preferred, certain androgen regimens have their advocates. Androgens continue to be helpful in occasional patients when used as a second-line therapy. Most hematologists have observed patients who appeared to respond or even to develop hormone dependence. Androgen therapy remains popular in developing countries because it is inexpensive, well tolerated, and seemingly effective. Various preparations of androgens in different doses have resulted in similar response rates of 35% to 60% after 6 months of therapy.

Useful androgens include nandrolone decanoate, oxymetholone, and danazol; unfortunately, their popularity and abuse by athletes have led to restrictions of their availability and manufacture. The hemoglobin response frequently is more impressive than improvements in granulocyte or platelet levels. An adequate trial is considered to be a full dose given for at least 3 months. Complications occur infrequently, although some are serious and can limit effective therapy, especially in elderly patients. The associated liver cholestasis is usually reversible. Hepatotoxicity (e.g., bile duct proliferation, peliosis, atypical hepatocyte hyperplasia, tumors) can occur but is less

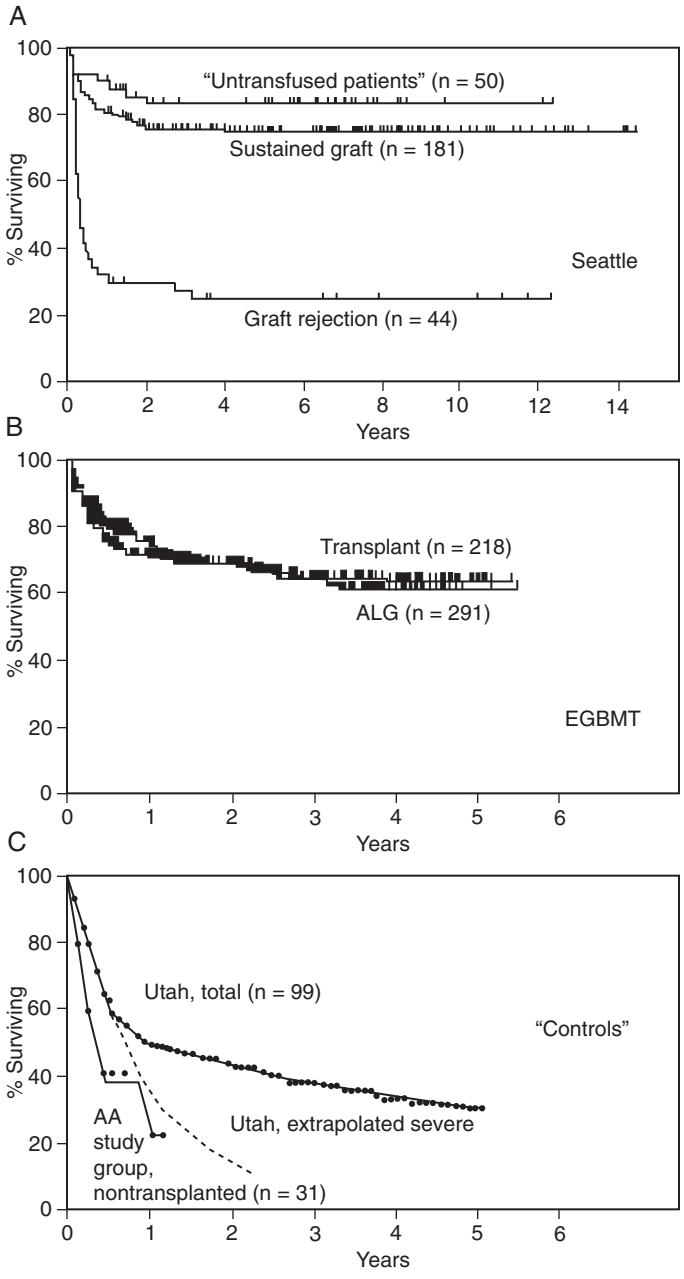

Figure 28-12 ACTUARIAL SURVIVAL RATES FOR PATIENTS WITH APLASTIC ANEMIA (AA). **A,** Data on bone marrow transplantation from the University of Washington. **B,** Data from the European Group for Bone Marrow Transplantation on bone marrow transplantation versus immunosuppression with antilymphocyte globulin (ALG). **C,** Natural history as indicated by survival with supportive and other treatments. Two groups are illustrated. Extrapolated survival curves for patients with severe disease are derived from retrospective reviews from the University of Utah of 101 records collected from the late 1940s to early 1970s. The patients received blood transfusions and, later in this period, also received platelets. Almost all were treated with corticosteroids, and one-half were also treated with androgens. Data for patients who did not receive transplants come from a multicenter study of the efficacy of bone marrow transplantation performed in the early 1970s; this control group was treated with androgens.

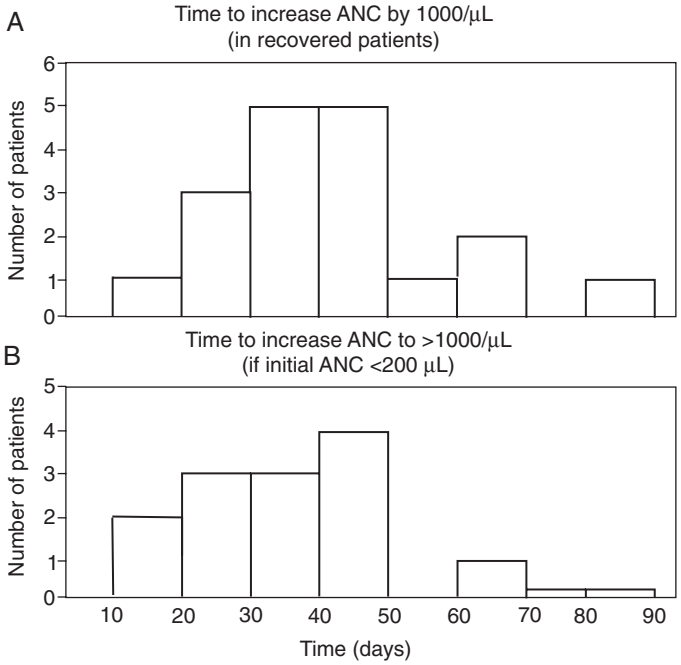

Figure 28-13 TIME TO RESPONSE AFTER TREATMENT WITH ANTILYMPHOCYTE GLOBULIN (ATG). **A,** Distribution of patients with severe aplastic anemia by time to achieve an increase in the absolute neutrophil count (ANC) of 1000 cells/mm^3. **B,** Distribution of patients with an initial ANC of less than 200 cells/mm^3 by time to achieve an ANC of 1000 cells/mm^3.

common with parenteral formulations. Children appear to tolerate high doses of androgens without lasting effects on growth or maturation.

Hematopoietic Growth Factors

Hematopoietic growth factor production is normal or increased in most patients with AA. Nevertheless, many patient are treated with pharmacologic high doses of cytokines, often with uncertain justification. G-CSF and GM-CSF in some cases can increase neutrophil numbers in patients with AA. In general, neutrophil responses to growth factors are transient, dependent on their continuous administration, and usually restricted to patients with less severe AA. Nevertheless, bilineage and trilineage responses have been observed. Children may be more sensitive to the effects of prolonged administration of G-CSF.

A concern has been the possibility that prolonged administration of G-CSF might increase the probability of late clonal disease, especially monosomy 7. In retrospective analyses of Japanese children and adults with severe AA, this syndrome appeared to occur most frequently among patients who had received growth factor; a modest increase in the risk of myelodysplasia and leukemia and monosomy 7 was also seen in European cases. The mechanism of G-CSF's relationship to monosomy may be selection of aneuploid cells bearing an isoform of G-CSF; these cells are less sensitive to G-CSF, but when triggered by the cytokine, they proliferate and do not differentiate.

Anemia and pancytopenia in rare patients have responded to prolonged administration of high doses of erythropoietin alone, GM-CSF and erythropoietin, and with IL-3 and G-CSF. In one randomized protocol, the combination of G-CSF and high doses of erythropoietin improved hemoglobin values, mainly in patients with moderate disease.

Growth factors have also been combined with definitive medical therapy for the purpose of improving neutrophil counts during the

early phase of immunosuppression. Neither small pilot trials nor large randomized studies have shown substantial benefit for the routine use of GM-CSF or G-CSF, in preventing infection, in improving the response rate to immunosuppression, or in survival.

New thrombopoietic factors may have utility in AA. In a recent small trial, an oral c-mpl agonist peptide, eltrombopag, increased not only platelet counts but led to erythrocyte and granulocyte improvement in almost half of 25 patients with chronic refractory severe AA. The mpl receptor is expressed by hematopoietic stem cells, and laboratory and clinical data indicate physiologic stimulation of stem cells by thrombopoietin.

In the absence of convincing evidence of short- or long-term benefit, growth factor use in AA is dictated by the individual physician's judgment. Hematopoietic growth factors are not definitive therapy of AA, and "therapeutic trials" in patients presenting with pancytopenia are seldom justified and most often delay appropriate treatments. A brief course of G-CSF or GM-CSF is appropriate in severely neutropenic patients who are persistently or seriously infected in the hope of achieving clinical benefit. Some patients with disease refractory to other forms of treatment can also receive prolonged courses of cytokines in the hope of raising the low neutrophil count. There is no justification for G-CSF use in patients with adequate neutrophil counts, yet many patients inexplicably are treated increase the granulocytes from levels of 500 to 1000/μL. Preferably, the use of growth factors over long treatment periods, especially in patients who are not severely neutropenic, should be in the context of a formal study. Physicians and patients should be aware of possibly significant risks associated with such treatment.

PROGNOSIS

The initial blood cell counts of a patient with AA are important indicators of prognosis. The popular "Camitta" criteria used to define severe disease are the presence of two of the following three: neutrophil count of less than 500 cells/μL, platelet count of less than 20,000 cells/μL, and corrected reticulocyte level of less than 1% (<40,000 cells/μL). In the more modern era, absolute reticulocytes (>25,000/μL) and absolute lymphocytes predicted good response to immunosuppression and survival.[26] The robustness of the platelet and reticulocyte response after immunosuppression also correlates with long-term survival. Clonal evolution, especially monosomy 7, is a poor prognostic factor, and age-adjusted telomere length of leukocytes at diagnosis may predict this serious complication.[27]

The rate of spontaneous recovery is difficult to estimate, but most observers believe it to be low. Untreated severe disease is almost invariably fatal. In contrast, moderate AA has a good prognosis, and some patients with minimal blood cell count depression recover normal blood cell counts with limited or no therapy.

CHAPTER 29

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Robert A. Brodsky

Paroxysmal nocturnal hemoglobinuria (PNH) is a clonal hematopoietic stem cell disorder that has fascinated hematologists for more than a century because of its protean clinical manifestations and captivating pathophysiology. One of the earliest descriptions of PNH was by Dr. Paul Strübing, who in 1882 described a 29-year-old Cartwright who presented with fatigue, abdominal pain, and severe nocturnal paroxysms of hemoglobinuria that were exacerbated by excess alcohol, physical exertion, and iron salts.[1] Strübing deduced that the hemolysis was occurring intravascularly as the patient's plasma turned red after severe attacks of hemoglobinuria. Decades later, his prescient deduction was confirmed. Later reports by Marchiafava and Micheli led to the eponym Marchiafava-Micheli syndrome, but it was Enneking, in 1925, who introduced the term *paroxysmal nocturnal hemoglobinuria*.

In 1937, Thomas Ham found that PNH erythrocytes were hemolyzed when incubated with normal, acidified serum. This seminal discovery resulted in the first diagnostic test for PNH, the acidified serum or Ham test. The cell lysis after acidified serum appeared to be complement dependent because heat inactivation abrogated the reaction; however, it was not until 1954, with the discovery of the alternative pathway of complement activation, that complement was formally proven to cause the hemolysis of PNH red blood cells (RBCs). After the emergence of specific diagnostic tests, additional disease manifestations such as venous thrombosis, bone marrow (BM) failure, and development of myelodysplastic syndromes (MDS) and acute leukemia were associated with PNH. These nonerythroid manifestations of the disease foreshadowed the discovery that PNH results from the clonal expansion of a mutated hematopoietic stem cell (HSC).

In the 1980s, roughly 100 years after Strübing's initial description of the disease, it was discovered that PNH cells display a global deficiency in a group of proteins affixed to the cell surface by a glycosylphosphatidylinositol (GPI) anchor. Interestingly, several of the missing proteins (e.g., CD55 and CD59) are important complement regulatory proteins. A few years later, the genetic mutation *(PIGA)* responsible for the GPI-anchor protein deficiency was discovered,[1,2] and most recently, a humanized monoclonal antibody that inhibits terminal complement activation has been shown to ameliorate hemolysis and disease symptoms in PNH patients.[3] Although the pathophysiology of many of PNH's clinical manifestations are now understood, the mechanism of thrombosis, the mechanism of clonal dominance, and the close association with aplastic anemia continue to be subjects of intense investigation. PNH is an extremely rare condition; however, the risk for developing PNH in patients with acquired aplastic anemia is 20% to 30%. In addition, more than half of patients with acquired aplastic anemia harbor a small- to moderate-sized PNH population at diagnosis.

PATHOPHYSIOLOGY

The Glycosylphosphatidylinositol Anchor

Covalent linkage to GPI is an important means of anchoring many cell-surface glycoproteins to the cell membrane. Alkaline phosphatase was the first GPI-anchor protein recognized after it was discovered that cell surface alkaline phosphatase could be removed by a bacterial enzyme, phosphatidylinositol-specific phospholipase C (PIPLC). PIPLC cleaved the phosphate from phosphatidylinositol (PI) and left the enzyme with full activity after its release, suggesting that the protein structure was unperturbed. This fundamental observation led to the discovery of dozens of GPI-anchored proteins.

The GPI anchor consists of a highly conserved glycan core (ethanoloamine-*P*-6Manα1-2Manα1-6Manα1-4GlcN) linked to the 6-position of the D-*myo*-inositol ring of PI (Fig. 29-1). The anchor is synthesized in the endoplasmic reticulum membrane and involves at least 10 reactions and more than 20 different genes (Table 29-1). The first step in GPI anchor biosynthesis is the transfer of *N*-acetylglucosamine (GlcNAc) from uridine diphosphate (UDP)-GlcNAc to PI to yield GlcNAc-PI. This step is catalyzed by GlcNAc-PI α1-6 GlcNAc transferase, an enzyme whose subunits are encoded by seven different genes: *PIGA, PIGC, PIGH, GPI1, PIGY, PIGP,* and *DPM2.* In the second step, GlcNAc-PI is deacetylated by the gene product of *PIGL* to form glucosamine (GlcN)-PI. GPI anchor assembly continues in the endoplasmic reticulum with acylation of the inositol and stepwise addition of mannosyl and phosphoethanolamine residues. The preassembled GPI is linked to nascent proteins that contain a C-terminal GPI-attachment signal peptide, displacing it in a transamidase reaction. The GPI-anchored protein then transits the secretory pathway to reach its final destination at the plasma membrane in compartments known as *lipid rafts*. If the GPI anchor is not attached to the protein, it is degraded intracellularly, probably in lysosomes.

Given the numerous gene products involved in GPI anchor assembly, it seemed improbable that PNH would be the consequence of a single genetic mutation. However, after intense scrutiny of this pathway, it became apparent that in all PNH cases, the defect could be attributed to mutations in the *PIGA* gene, whose product is essential for the first step of GPI anchor biosynthesis. Later it was determined that the *PIGA* gene is on the X chromosome and that its product is part of a complex that transfers *N*-acetylglucosamine to PI to form GlcNAc-PI. Thus, a single "hit" will generate a PNH phenotype because males have only one X chromosome, and in females, one X chromosome is inactivated through lyonization. Conceivably, a mutation in any one of the genes in this pathway would cause the disease; however, other genes involved in GPI anchor biosynthesis are located on autosomes (see Table 29-1). Inactivating mutations in these genes would have to occur on both alleles to produce the PNH phenotype. Congenital *PIG-A* mutations resulting in an absence of GPI anchored proteins are embryonic lethal; however, germline mutations have been described in mannosyltransferases in the GPI pathway. A *PIGM* promoter mutation causing reduced GPI-linked protein expression was described in two consanguineous families. Individuals presented with portal and hepatic vein thrombosis and persistent seizures. Missense *PIGV* mutations cause hyperphosphatasia mental retardation syndrome (HPMR).

Acetylcholinesterase from erythrocytes and alkaline phosphatase from leukocytes were the first GPI-anchored proteins shown to be missing in PNH. Since then, more than a dozen GPI-anchored proteins with heterogeneous expression on hematopoietic cells have been found to be missing in PNH (Table 29-2). The functions of these cell surface GPI-anchored proteins are manifold; they can serve as

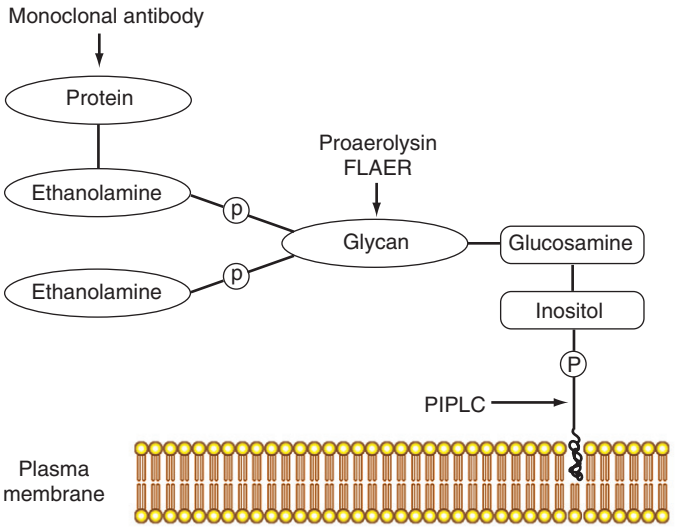

Figure 29-1 STRUCTURE OF THE GLYCOSYLPHOSPHATIDYLINOSITOL (GPI) ANCHOR. Phosphatidylinositol is inserted into the lipid bilayer of the plasma membrane. The glycan core, which serves as the binding site for aerolysin, proaerolysin, and FLAER, consists of a molecule of *N*-glucosamine, three molecules of mannose, and one molecule of ethanolamine. The representative protein (e.g., CD55, CD59, and so on) is covalently attached through an amide bond to an ethanolamine on the terminal mannose. Individual monoclonal antibodies used for the diagnosis of PNH (e.g., CD55, CD59, and so on) bind to the protein but not the GPI anchor. Phosphatidylinositol-specific phospholipase C (PIPLC) cleaves the phosphate from phosphatidylinositol and leaves the enzyme with full activity after its release *P*, Phosphate.

complement regulatory proteins, enzymes, blood group antigens, receptors, and adhesion molecules. Membrane inhibitor of reactive lysis (CD59) and decay accelerating factor (CD55)—both complement regulatory proteins—are the most widely expressed GPI-anchored proteins and can be found on all hematopoietic lineages, including $CD34^+CD38^-$ progenitor cells.[4] Certain proteins, CD58 (LFA3) and CD16 (FcγRIII), may exist in both GPI-linked and transmembrane forms.

PIGA Gene

Investigators in Osaka, Japan, first identified the gene that was defective in PNH.[5] The gene was isolated by expression cloning and named *PIGA* (phosphatidylinositol–glycan complementation class A). *PIGA* was then cloned into an expression vector and transfected into GPI-deficient cell lines derived from PNH patients; cell surface expression of all the missing GPI-anchored proteins was restored, confirming that *PIGA* mutations are responsible for causing PNH. Since this seminal discovery, somatic mutations of the *PIGA* gene have been found in all PNH patients to date. Little to no GPI anchor is made when the *PIGA* gene is mutated. Consequently, the translated protein (e.g., CD59, CD55, and so on) residing in the cisterna of the endoplasmic reticulum cannot be attached to the GPI anchor and is degraded in situ.

The human *PIGA* gene contains 6 exons and 5 introns and extends over 17 kb (Fig. 29-2); it encodes for a protein that contains 484 amino acids (60 kd). In humans, a single copy of the gene is located on the short arm of the X chromosome (Xp22.1), although an intronless pseudogene has been found on chromosome 12q21. A wide range of somatic mutations interspersed throughout the entire coding region of the *PIGA* gene have been described in PNH patients. There are no true mutational "hot spots," although exon 2, which contains almost half of the coding region, is the exon where most mutations occur. Most *PIGA* mutations are small insertions or deletions, usually one or two base pairs, which result in a frameshift in the coding region and consequently a shortened, nonfunctional product. Although *PIGA* function is abolished by these frameshift mutations, missense mutations, where the product of the mutated *PIGA* gene has some residual activity, have also been described. In most patients studied, a single (monoclonal) *PIGA* mutation has been discovered. However, two different mutations (biclonal)—and in one case, four separate *PIGA* mutations—have been found in PNH patients.

†Genes involved in the transamidase reaction.

Paroxysmal Nocturnal Hemoglobinuria Stem Cell

Paroxysmal nocturnal hemoglobinuria is a clonal hematopoietic disorder. The first evidence to support the notion that PNH arises through the mutation of an abnormal multipotent HSC was derived from glucose 6-phosphate dehydrogenase studies of the RBCs of women with PNH. Subsequently, flow cytometric analyses revealed that all hematopoietic lineages—myeloid, erythroid, and lymphoid—were involved. Furthermore, *PIGA* mutations found in granulocytes match those found in other lineages, and $CD34^+CD38^-$ progenitor cells have been shown to be missing GPI-anchored proteins in PNH patients. Thus, the "hit" in PNH clearly involves a multipotent HSC and appears to involve an earlier stem cell than diseases such as chronic myelogenous leukemia, MDS, or acute leukemia. In the latter disorders, B cells are sometimes derived from the leukemia clone, but T cells are seldom involved. In PNH, both B cells and T cells have been shown to be derived from the malignant clone.[6]

Table 29-2 Cell Surface Glycosylphosphatidylinositol-Anchored Protein Absent on Paroxysmal Nocturnal Hemoglobinuria Blood Cells

Antigen	Hematopoietic Lineage	Classification
CD55—decay accelerating factor	All blood cells	Complement regulator
CD59—membrane inhibitor of reactive lysis	All blood cells	Complement regulator
CD58—lymphocyte function associated antigen-3	All blood cells	Adhesion molecule
Acetylcholinesterase	RBCs	Enzyme
CD14—monocyte differentiation antigen	Granulocytes, monocytes, macrophages	Endotoxin-binding receptor
CD16—Fcγ receptor III	Granulocytes, NK cells	Receptor
CD66b	Granulocytes	Adhesion
Neutrophil alkaline phosphatase	Granulocytes	Enzyme
CD87—urokinase (plasminogen activator) receptor	Monocytes, granulocytes	Receptor
Leukocyte alkaline phosphatase	Granulocytes	Enzyme
CDw52—Campath-1 antigen	Lymphocytes, monocytes	Unknown
CD24	B lymphocytes, granulocytes	B-cell differentiation
CD48	All leukocytes	Adhesion molecule
CD73—ecto-5'-nucleotidase	Some B and T lymphocytes	Enzyme
Dombrock-Holley/Gregory-bearing protein	Red cells	Blood group antigen
Folate receptor	Myeloid and erythroid cells	Receptor

NK, Natural killer; *RBC,* red blood cell.

Paroxysmal Nocturnal Hemoglobinuria Red Blood Cells

Paroxysmal nocturnal hemoglobinuria cells can display one of three phenotypes (Fig. 29-3): cells with normal expression of GPI-anchored proteins (type I cells), cells with intermediate expression of GPI anchor proteins (type II cells), and cells with no expression of GPI anchor proteins (type III cells). These three populations are most easily seen in the erythrocyte and granulocyte populations. Patients with three discreet granulocyte populations (type I, type II, and type III cells) usually have more than one PNH clone. Whereas the type II cells are usually the consequence of a missense mutation, the type III cells commonly result from frameshift mutations caused by small base pair insertions or deletions. However, in many PNH patients, the type II cells are not a distinct population but represent a "spectrum" between the type III and type I cells (see Fig. 29-3).

CLINICAL FEATURES

Hemolytic Anemia and Hemoglobinuria

Hemolysis in PNH results from the increased susceptibility of PNH RBCs to complement. Complement consists of a battery of proteins

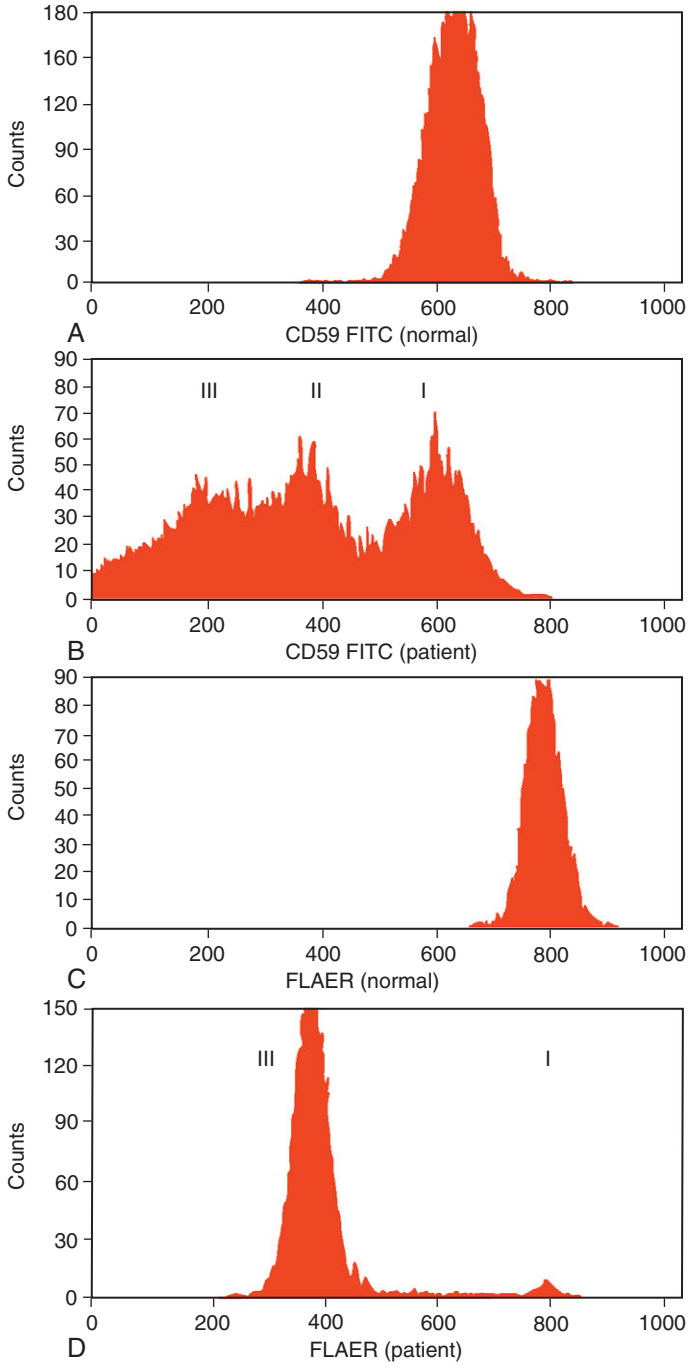

Figure 29-2 FLOW CYTOMETRIC ANALYSIS OR PERIPHERAL BLOOD CELLS FROM A PATIENT WITH PAROXYSMAL NOCTURNAL HEMOGLOBINURIA (PNH). **A,** Fluorescence intensity of erythrocytes from a healthy control participant after staining with anti-CD59. **B,** Fluorescence intensity of erythrocytes from an untransfused PNH patient after staining with anti-CD59. Type II cells are "blended" between the type I (normal) and type III cells. **C,** Fluorescence intensity of granulocytes from a healthy control participant stained with FLAER. **D,** Fluorescence intensity of granulocytes from the same PNH patient as in **B** after staining with FLAER. Note that the granulocytes are almost exclusively type III cells. A small population of type I granulocytes is present. *FITC,* Fluorescein isothiocyanate.

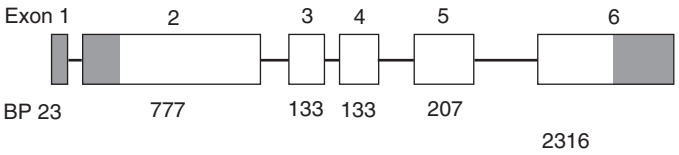

Figure 29-3 STRUCTURE OF THE HUMAN *PIGA* GENE. *Boxes* represent exons; intervening *lines* represent introns. *Shaded areas* show noncoding regions.

that circulate in the plasma. These proteins are part of the innate immune system and are important for antibody-mediated immunity. Normally, membrane proteins regulate the activation of the complement system and protect cells from the deleterious effects of activated complement. PNH RBCs are more vulnerable to complement-mediated lysis because of a reduction or complete absence of membrane inhibitor of reactive lysis (CD59) and decay accelerating factor (CD55), both of which are GPI anchored.

CD59 is a 19,000-molecular-weight glycoprotein that directly interacts with the membrane attack complex (MAC) to prevent lytic pore formation by blocking the aggregation of C9.[7] CD55, a 68,000-molecular-weight glycoprotein, functions to accelerate the rate of destruction of membrane-bound C3 convertase. Hence, CD55 reduces the amount of C3 that is cleaved, and CD59 reduces the number of MAC that is formed. Of the two, CD59 is more important in protecting cells from complement. RBCs from individuals with the Inab phenotype, a blood group antigen, lack CD55, yet these individuals have no clinical hemolysis. In contrast, a patient with a congenital deficiency of CD59 had a compensated hemolytic anemia. Furthermore, incorporation of CD59 onto PNH erythrocytes was shown to ameliorate acidified serum lysis to a greater extent than incorporation of CD55.

The classic manifestation from which PNH derives its name—paroxysmal bouts of reddish, brownish, or "cola-colored" urine that strikes predominantly overnight—is described by a minority of PNH patients. Most PNH patients have no noticeable hemoglobinuria or have intermittent episodes of hemoglobinuria with no relationship to the time of day. Early speculation that the nocturnal hemoglobinuria was a function of a mild drop in pH that occurs with sleep has not been validated. Patients with a history of hemoglobinuria are more likely to have a large PNH clone and less likely to have markedly hypocellular BM.

Although hemolysis is often the most conspicuous feature in patients with classical PNH, many patients, particularly those with coexisting BM failure, exhibit mild to barely detectable hemolysis. The hemoglobin concentration can range from normal to severely depressed. The reticulocyte count is often elevated but usually lower than expected for the degree of anemia. Patients with PNH manifest all of the usual clinical and laboratory signs of chronic hemolytic anemia, including weakness, fatigue, pallor, and dyspnea on exertion. In patients with prominent hemolysis, the magnitude of fatigue can be out of proportion to the degree of anemia. Morphologically, the RBCs appear normal, although some cases display mild to moderate poikilocytosis and anisocytosis. The haptoglobin levels are usually low, and the lactate dehydrogenase (LDH) level is frequently elevated, sometimes greater than 3000 IU/L, depending on the degree of hemolysis.

Multiple factors influence the degree of hemolysis in PNH, including the size and type of the PNH clone and the degree of complement activation. In general, the percentage of PNH erythrocytes correlates with the degree of hemolysis. However, the type of PNH erythrocytes may also influence the degree of hemolysis. Type III erythrocytes are more readily lysed than type II erythrocytes and almost always constitute a larger percentage of the PNH RBCs. Thus, patients with a large percentage of type III erythrocytes tend to have more hemolysis than patients with a large percentage of type I or type II cells. Finally, hemolysis is frequently exacerbated by infections (especially gastrointestinal infections), surgery, strenuous exercise, excessive alcohol intake, blood transfusions, and anything else that increases complement activation.

Smooth Muscle Dystonia and Nitric Oxide

Many clinical manifestations of PNH are readily explained by hemoglobin-mediated nitric oxide scavenging.[8] Failure of complement regulation on the PNH erythrocyte membrane leads to intravascular hemolysis, resulting in the release of large amounts of free hemoglobin into the plasma. Free plasma hemoglobin leads to increased consumption of nitric oxide, resulting in manifestations that include fatigue, abdominal pain, esophageal spasm, erectile dysfunction, and possibly thrombosis. Indeed, hemoglobinuria, thrombosis, erectile dysfunction, and esophageal spasm are more common in patients with large PNH populations (>60% of granulocytes) than in patients with relatively small PNH populations. In a study of 49 PNH patients diagnosed using flow cytometry, Moyo and colleagues[5] demonstrated that large PNH clones were associated with an increased risk for thrombosis, hemoglobinuria, abdominal pain, esophageal spasm, and male impotence. Thus, many of the clinical manifestations of PNH appear to be a direct consequence of intravascular hemolysis, leading to the release of free hemoglobin, scavenging of nitric oxide, and smooth muscle dystonias.

Renal Manifestations

Patients with PNH can experience renal manifestations that resemble those observed with sickle cell anemia. Perturbed tubular function and declining creatinine clearance are found in a high percentage of patients. Radiologically, patients may exhibit large kidneys, cortical infarcts, cortical thinning, and papillary necrosis. PNH patients display marked hemosiderin deposition in the proximal tubules; however, microvascular thrombosis can be responsible for many of the renal abnormalities in PNH.[9] Acute renal failure after massive hemolysis occurs infrequently and usually resolves in days to weeks.

Thrombosis and Paroxysmal Nocturnal Hemoglobinuria

Thrombosis is an ominous complication of PNH and was the leading cause of death before the availability of pharmacologic complement inhibition. Thrombosis occurs in approximately 40% of PNH patients and most commonly involves the venous system, but arterial clots may also occur. Patients with a large percentage of PNH cells and classical symptoms (hemolytic anemia and hemoglobinuria) have a greater propensity for thrombosis than patients with a small percentage of PNH cells. According to logistic regression modeling, for a 10% change in PNH clone size, the odds ratio for risk of thrombosis is estimated to be 1.64. Patients with PNH granulocyte clones of greater than 60% appear to be at greatest risk for thrombosis. The mechanism of thrombosis in PNH is not entirely understood and is probably multifactorial, but similar to other manifestations of the disease, it is probably related to the GPI anchor protein deficiency and activation of complement. Indeed, C5a is proinflammatory and may increase the risk for thrombosis. Furthermore, nitric oxide depletion (as a consequence of intravascular hemolysis and nitric oxide scavenging) has been associated with increased platelet aggregation, increased platelet adhesion, and accelerated clot formation. In an attempt to repair damage, PNH platelets undergo exocytosis of the complement attack complex. This results in the formation of microvesicles with phosphatidylserine externalization, a potent in vitro procoagulant. These prothrombotic microvesicles have been detected in the blood of PNH patients. Fibrinolysis can also be perturbed in PNH given that PNH blood cells lack the GPI-anchored urokinase receptor. Lastly, tissue factor pathway inhibitor (TFPI), a major inhibitor of tissue factor, has been shown to require a GPI-anchored chaperone protein for trafficking to the endothelial cell surface. Although the mechanism of thrombosis in PNH is not entirely clear, the sites of venous thrombosis in PNH are manifold with the abdominal veins and the cerebral veins being the most commonly involved regions.

Liver

Hepatic vein thrombosis (Budd-Chiari syndrome) is a common site of thrombosis in PNH and may be fatal without appropriate therapy. The clinical manifestations of hepatic vein thrombosis include abdominal pain, hepatomegaly, jaundice, ascites, and weight gain. The onset of symptoms can be abrupt or insidious. Hepatic vein thrombosis in PNH tends to inexorably progress with periodic exacerbations followed by intervals of relatively stable disease. Although some patients live many years with the condition, it frequently results in death unless complement inhibition or BM transplantation (BMT) is initiated. The best noninvasive tests to confirm the diagnosis include computed tomography scanning, magnetic resonance imaging (MRI), and ultrasonography. Thrombosis can involve the small hepatic veins, large-sized hepatic veins, or both. Thrombolytic therapy has been used successfully to restore venous patency and reverse the hepatic congestion; however, because of the potential danger of this approach, it should be used judiciously. Patients with acute-onset disease, preserved platelet counts (>50,000 cells/mm^3), and large vessel involvement are the best candidates for thrombolysis. For patients with massive ascites who are not suitable candidates for thrombolytic therapy, transjugular intrahepatic portal-systemic shunting or surgical shunting can successfully palliate some patients. Orthotopic liver transplantation was once considered contraindicated in PNH, but now that the thrombotic risk can be mitigated using complement inhibition, this is no longer true. Long-term survival after liver transplantation and eculizumab administration has been reported.[9]

Portal vein thrombosis is also common in PNH and can occur with or without hepatic vein thrombosis. Patients frequently present with nausea, vomiting, abdominal pain, and liver dysfunction. Management is similar to that of hepatic vein thrombosis.

Other Abdominal Veins

Venous thrombosis in PNH has been described in all abdominal and retroperitoneal venous systems, including the splenic veins, mesenteric veins, renal veins, and inferior vena cava. Thrombosis of minor veins can also occur and can be difficult to diagnose because of the protean manifestations and their relapsing and remitting nature. Often such patients present with recurrent, severe abdominal pain crises sometimes mimicking intestinal obstruction. The consequence of these microthromboses can sometimes be visualized with esophagogastroduodenal endoscopy or colonoscopy. Patients with intestinal thromboses can present with ischemic colitis and can be misdiagnosed as having Crohn disease. Upper gastrointestinal bleeding can be caused by esophageal or gastric varices that develop as a consequence of portal hypertension or splenic vein thrombosis.

Cerebral Veins

Cerebral veins, particularly the sagittal veins and sinuses, are also highly prone to thrombosis in PNH. Patients can present with severe headaches or focal neurologic deficits depending on the location of the thrombosis. Similar to hepatic vein thrombosis, cerebral vein thrombosis is an ominous complication that can result in substantial morbidity and mortality. MRI to carefully examine the cerebral blood flow is helpful in establishing the diagnosis.

Other Sites

Dermal venous thrombosis can occur virtually anywhere on the body. Patients usually complain of pain, discolorations, and swelling. The lesions can reach several centimeters in diameter and are firm and tender. Necrosis and the formation of a black eschar can occur. Anticoagulation and warm compresses can ameliorate the attacks. Pulmonary emboli and deep venous thrombosis have also been reported in PNH but are uncommon; arterial thrombosis is rare.

CLONALITY AND BONE MARROW FAILURE

PIGA Mutations in Aplastic Anemia and Myelodysplastic Syndrome

Small to moderate PNH clones are found in up to 70% of patients with acquired aplastic anemia, demonstrating a pathophysiologic link between these disorders.[10,11] Typically, less than 20% GPI anchor protein–deficient granulocytes are detected in aplastic anemia patients at diagnosis, but occasional patients can have larger clones. DNA sequencing of the GPI anchor protein–deficient cells from aplastic anemia patients reveals clonal *PIGA* gene mutations that arise from a multipotent HSC. Moreover, many of these patients exhibit expansion of the *PIGA* mutant clone and progress to clinical PNH. Although it was once thought that PNH evolving from aplastic anemia is more benign than classical PNH, this observation is probably a consequence of lead time bias because many of these patients eventually develop classical PNH symptoms.

GPI anchor protein–deficient cells have also been reported in patients with MDS, but sequencing of the *PIGA* gene to establish clonality has not been performed in most of these studies. MDS patients reported to have small PNH populations tend to be classified as refractory anemia and often have the following characteristics: a hypocellular marrow, human leukocyte antigen (HLA)-DR15 positivity, normal cytogenetics, moderate to severe thrombocytopenia, and a high likelihood of response to immunosuppressive therapy. Thus, it is possible that many of these patients have moderate aplastic anemia rather than MDS. Distinguishing hypoplastic MDS from aplastic anemia is often difficult; however, quantitative analysis of BM CD34 positive cells is useful for discriminating between these two entities.

PIGA Mutations in Healthy Controls

Paroxysmal nocturnal hemoglobinuria is an uncommon disease, with only two to five new cases per million U.S. inhabitants annually; however, *PIGA* mutations can be found in the blood from virtually all healthy control participants. Araten and coworkers[7] used flow cytometric analysis of blood from nine healthy control participants and found an average of 22 GPI anchor protein–deficient granulocytes per 10^6 cells, yet none of these subjects developed PNH. GPI anchor protein–deficient lymphocytes have also been detected in patients with lymphoid malignancies or rheumatoid arthritis after treatment with alemtuzumab (Campath-1H). Alemtuzimab is a monoclonal antibody that recognizes CD52, a GPI-anchored protein expressed on monocytes, B cells, and T cells. None of these patients developed PNH; furthermore, when alemtuzimab was discontinued, the GPI anchor protein–deficient cells regressed.

How can such a common mutation, *PIGA,* be so specific for PNH yet so rarely result in disease? One hypothesis to explain the close relationship between PNH and aplastic anemia, and the mechanisms whereby the PNH clone achieves dominance, involves a "two-step" model. This model proposes that HSCs randomly and spontaneously acquire *PIGA* mutations at a very low frequency (step one). Step two in this model proposes that the immunologic attack that targets HSCs in aplastic anemia spares PNH cells, ostensibly because they lack GPI-anchored proteins.[12] Indeed, *PIGA* mutant cells are found at low frequency in most healthy control participants. More recent data suggest that most, if not all, *PIGA* mutations in healthy control participants arise from colony-forming cells rather than HSCs.[6] Because colony-forming cells lack self-renewal capacity and only produce new blood cells for a few months, *PIGA* mutations arising in these cells do not result in PNH. Similarly, the *PIGA* mutations found in some MDS patients also arise in colony-forming cells, explaining why MDS patients with small populations of PNH-like cells seldom, if ever, progress to PNH. Furthermore, no direct evidence supports a GPI-anchored protein being the target of the

immune attack in aplastic anemia. Importantly, this two-step model does not explain the similarly high incidence of MDS in patients with aplastic anemia.

An alternative hypothesis that could explain the predisposition of patients with aplastic anemia to develop both PNH and MDS has been proposed.[13] MDS and PNH evolving in the setting of aplastic anemia could be analogous to the *field cancerization effect* described in aerodigestive and other solid tumors to explain second primary tumors in the affected tissue. That is, a single insult to the BM, such as generalized toxic damage or a genetic predisposition, may be responsible for bringing about different forms of BM disorders; these disorders can occur alone, simultaneously, or sequentially. In aplastic anemia, the BM injury may primarily trigger an autoimmune attack on the hematopoietic stem progenitor compartment, perhaps by exposing cryptic epitopes through molecular mimicry or by sending a "danger" signal. In primary PNH or MDS, the injury may primarily produce a genetic mutation that leads to clonal dominance of the affected clone. In other patients, BM injury may induce both an autoimmune hematopoietic attack and a clonal genetic mutation that presents either simultaneously or sequentially. Examples of simultaneous presentation are the aplastic anemia–PNH overlap and hypoplastic MDS. A third hypothesis proposes that additional mutations occurring in *PIGA* mutant stem cells are required for clonal expansion PNH. These hypotheses may not be mutually exclusive; thus, further investigation is needed to fully understand the mechanism of clonal dominance in PNH.

Clinical observations also provide clues to understanding clonal dominance in PNH and the relationship between aplastic anemia and PNH. Up to 30% of patients with aplastic anemia treated with conventional immunosuppressive therapy (antithymocyte globulin [ATG] and cyclosporine) develop PNH or MDS, usually several years after therapy. In contrast, allogeneic BMT appears to eliminate the risk for developing PNH in patients with aplastic anemia. These data suggest that secondary clonal disorders (PNH and MDS) are part of the natural history of aplastic anemia. Although immunosuppressive therapy unequivocally prolongs survival, it does not prevent these late complications.

Clonal Transformation

Patients with PNH, similar to those with aplastic anemia and MDS, are at increased risk for clonal transformation; however, the incidence of leukemic transformation in PNH is less than that of MDS. Abnormal cytogenetics can be found in up to 20% of patients with PNH. MDS and acute myeloid leukemia are the most common malignancies to evolve from PNH; the leukemic cells may arise from the GPI anchor–deficient clone in many but not all cases.

NATURAL HISTORY

The natural history of PNH before the era of anticomplement therapy ranged from indolent to severely debilitating and life threatening.[14-16] The ability to pharmacologically interfere with terminal complement appears to have altered the natural history of the disease by markedly decreasing the thrombosis rate. Females and males are equally affected with the median age of diagnosis being 40 years old. Without therapy, the median survival from time of diagnosis is 10 to 20 years. Thrombosis, severe pancytopenia, evolution to MDS or leukemia, older age, and thrombocytopenia at diagnosis portend a poor prognosis. Older literature, in which patients were diagnosed with PNH based on the Ham test or sucrose hemolysis test, reported on the occurrence of spontaneous long-term remissions in up to 10% of PNH cases; however, in patients diagnosed by flow cytometry, the spontaneous remission rate is much less common. In summary, eculizumab, a monoclonal antibody that inhibits terminal complement, appears to have altered the natural history of PNH by reducing the incidence of fatal thrombotic events.

LABORATORY EVALUATION

Blood

Peripheral blood counts in PNH patients vary from severe pancytopenia to normal. Virtually all patients present with anemia, frequently with mild macrocytosis. Thrombocytopenia and neutropenia are also common. A mild to moderate reticulocytosis is usually present in patients with the classical form of the disease; however, in patients with hypoplastic PNH (also referred to as *aplastic anemia/PNH overlap*), the reticulocyte count can be low for the degree of anemia. Similarly, in patients with hypoplastic PNH, the biochemical profile can be normal, but in patients with large PNH clones, the indirect bilirubin and LDH level are significantly elevated. In patients with vigorous hemolysis, it is common for the laboratory to report the specimen as "hemolyzed."

Bone Marrow

Bone marrow cellularity can be hypocellular, normocellular, or hypercellular. In patients with classical PNH (not arising from or coinciding with aplastic anemia), the marrow is usually normocellular to hypercellular with erythroid hyperplasia. Mild to moderate dyserythropoiesis is common. Stainable iron is frequently absent because of iron loss associated with the intravascular hemolysis. Cytogenetic abnormalities can be found in a small number of patients.

DIAGNOSIS

Complement-Based Assays

The Ham test and the sucrose hemolysis test (sugar water test) were two of the first assays used to diagnosis PNH. Both assays are performed on erythrocytes and discriminate PNH cells from normal cells based on a differential sensitivity to the hemolytic action of complement. In the Ham test, complement is activated by acidification of the serum. This results in lysis of PNH erythrocytes but not normal erythrocytes. The Ham test is relatively specific for PNH but is not very sensitive.

Complement is also activated in a low ionic strength sucrose-containing medium. Preferential lysis of PNH erythrocytes through the activation of complement in this sucrose-containing medium forms the basis for the sugar water test. This assay is easier to perform and is more sensitive than the Ham test but not as specific; other hemolytic anemias and even leukemias can produce false-positive results. The complement lysis assay in which complement is activated with antibody also detects PNH erythrocytes. These complement-based RBC assays are important from a historical perspective but should no longer be used to establish the diagnosis of PNH.

GPI Anchor-Based Assays

Most laboratories use monoclonal antibodies against specific GPI-anchored proteins in conjunction with flow cytometry to diagnose PNH.[17,18] Anti-CD59 is most commonly used because it is widely expressed and is displayed on all hematopoietic lineages. Anti-CD55, anti-CD14, anti-CD16, anti-CD67, and a variety of other monoclonal antibodies can also be used to establish the diagnosis. Flow cytometry offers several advantages over complement-based assays for diagnosing PNH: It measures the size of the PNH clone in the various cell lineages, it is more sensitive and specific, and it is less affected by blood transfusions. It is noteworthy that rare congenital deficiencies of CD59 and CD55 can lead to a false-positive test results for PNH if only one monoclonal antibody is used. This, coupled with the variable expression of GPI-anchored proteins on different hematopoietic lineages, accounts for the recommendation

that at least two different monoclonal antibodies directed against two different GPI-anchored proteins on at least two different cell lineages should be used to diagnose a patient with PNH. Solely screening patients' RBCs for PNH can lead to falsely negative tests, especially in the setting of a recent hemolytic episode or a recent blood transfusion. Because granulocytes and monocytes have short half-lives and are not affected by blood transfusions, the percentage of PNH cells in these lineages best reflects the size of the PNH stem cell pool.

Aerolysin Assays

A fluorescein-labeled proaerolysin variant, FLAER, is commonly used in conjunction with monoclonal antibodies in a flow cytometric assay to diagnose PNH.[19] Aerolysin is the principal virulence factor of the bacterium *Aeromonas hydrophila*. It is secreted as an inert protoxin termed *proaerolysin* that binds selectively and with high affinity to a GPI anchor. After binding to its receptor (the glycan portion of the GPI anchor), the C-terminal peptide of proaerolysin is cleaved by cell proteases. This activates the toxin and leads to the formation of heptameric channels that insert into the membrane and kill the cell. PNH cells are resistant to aerolysin and proaerolysin because PNH cells lack GPI-anchored proteins.[20] FLAER binds to the GPI anchor without forming channels and gives a more accurate assessment of the GPI-anchor deficit in PNH than anti-CD59. Because the GPI anchor is the major determinant for binding FLAER, it allows for the direct assessment of GPI anchor expression on virtually all cell lineages. RBCs are a notable exception; this may be because both normal and PNH RBCs express large amounts of glycophorin, a protein shown to bind aerolysin weakly. Nevertheless, in mononuclear cells, FLAER eliminates the need for multiple lineage-specific monoclonal antibodies. These properties make FLAER more reliable for detecting the small PNH populations often found in patients with aplastic anemia.

THERAPY

Some PNH patients can be managed conservatively with watchful waiting. The major exceptions are patients with hypoplastic PNH (especially those who also meet criteria for severe aplastic anemia) and patients with life-threatening thromboses or debilitating hemolysis and smooth muscle dystonias.[21] Cytopenias in patients with hypoplastic PNH are usually caused by immune suppression of hematopoiesis; thus, the management of these patients should be similar to those with acquired aplastic anemia. Classical PNH patients manifesting with recurrent thrombosis or severe intravascular hemolysis often require either complement inhibition or sometimes BMT.

Immunosuppressive Therapy

Patients with PNH with hypocellular BM, low reticulocyte count, and pancytopenia (hypoplastic PNH) frequently respond to immunosuppressive therapy. The response rate in this group is more than 50%. In fact, finding a minor population of PNH-like cells in severe aplastic anemia may predict for response to immunosuppressive therapy. The impaired hematopoiesis that occurs in hypoplastic PNH may respond to ATG or cyclosporine, but the PNH clone is usually not affected. In some cases, immunosuppressive therapy has ameliorated the aplasia but with preferential expansion of the PNH clone. Immunosuppressive therapy does not appear to benefit patients with classical PNH.

Management of Anemia

The cause of anemia in PNH is often multifactorial. In patients with hypoplastic PNH, BM failure is the major etiologic factor for anemia. Patients with hypoplastic PNH may respond to immunosuppressive therapy. However, in patients with cellular BM, elevated reticulocyte counts, and high LDH level (classical PNH), intravascular hemolysis is the major mechanism of anemia. Terminal complement inhibition is highly effective for decreasing intravascular hemolysis. Iron deficiency caused by intravascular hemolysis can also contribute to the anemia of PNH; thus, in patients with absent iron stores, iron replacement therapy is indicated. Folic acid supplementation is also recommended in PNH because of the high RBC turnover. Erythropoietin is rarely beneficial in PNH. Often RBC transfusions are required to treat severe anemia. PNH patients should receive group-specific blood and blood products. Washing the RBCs with saline, once advocated to minimize hemolysis after transfusion in PNH, is unnecessary.

Eculizumab

Eculizumab is a humanized monoclonal antibody against C5 that inhibits terminal complement activation (Fig. 29-4).[3,22,23] Because C5 is common to all pathways of complement activation, blockade aborts progression of the cascade regardless of the stimuli. Moreover, prevention of C5 cleavage blocks the generation of the potent proinflammatory and cell lytic molecules C5a and C5b-9, respectively (see Fig. 29-4). Importantly, C5 blockade preserves the critical immunoprotective and immunoregulatory functions of upstream components that culminate in C3b-mediated opsonization and immune complex clearance. In 2007, the U.S. Food and Drug Administration approved eculizumab for use in PNH based pon its efficacy in two phase III clinical trials. Eculizumab is highly effective in reducing intravascular hemolysis in PNH; it does not stop extravascular hemolysis and does not treat BM failure. Thus, eculizumab is most effective in patients with classical PNH. Treatment with eculizumab decreases or

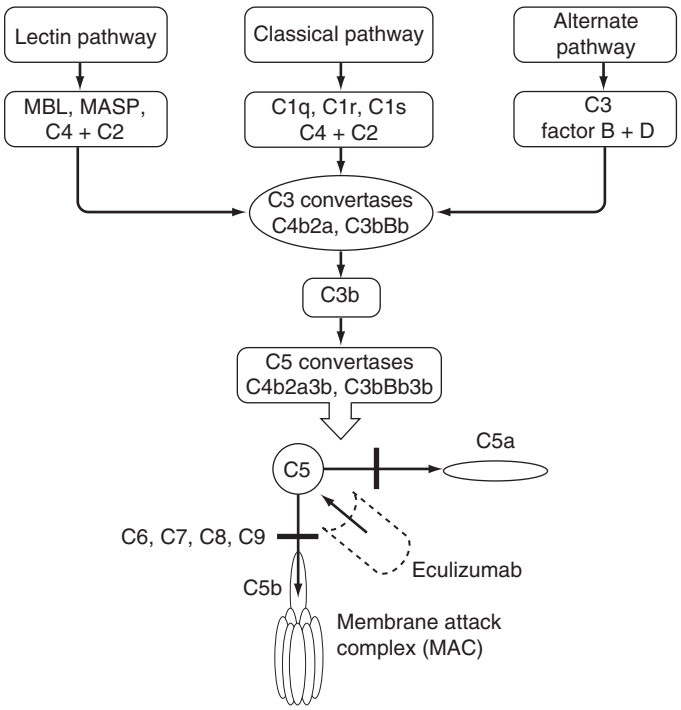

Figure 29-4 OVERVIEW OF THE COMPLEMENT CASCADE. Classic, alternative, and lectin pathways converge at the point of C3 activation. The lytic pathway is initiated with the formation of C5 convertase and leads to the assembly of the C5, C6, C7, C8, (*n*) C9 membrane attack complex. Eculizumab is a monoclonal antibody that binds to C5, thereby preventing the formation of C5a and C5b. C5b is the initiating component of the MAC. *FITC,* Fluorescein isothiocyanate; *MASP,* mannan-binding lectin associated service protease; *MBL,* Mannose binding lectin.

eliminates the need for blood transfusions in most patients, improves quality of life, and reduces the risk of thrombosis. Two weeks before starting therapy, all patients should be vaccinated against *Neisseria meningitides* because inhibition of complement at C5 increases the risk for developing infections with encapsulated organisms, particularly *N. meningitides* and *Neisseria gonorrhoeae*. Eculizumab is administered intravenously at a dose of 600 mg weekly for the first 4 weeks. On week five, the dose is increased to 900 mg IV, and thereafter the drug is dosed at 900 mg intravenously every 14 + 2 days. Rare patients will break through at this dosage and require a higher dose of eculizumab. Eculizumab is generally safe and well tolerated but must be continued indefinitely because it does not treat the underlying cause of the disease. The most common side effect, headache, occurs in roughly 50% of patients after the first dose or two but rarely occurs thereafter. *Neisserial* sepsis is the most serious complication of eculizumab therapy; thus, it is imperative to remind patients that they have a 0.5% yearly risk of acquiring *Neisserial* sepsis even after vaccination. Moreover, patients should be revaccinated against *N. meningitidis* every 3 to 5 years after starting eculizumab.

Indications for Therapy

Not all patients with a diagnosis of PNH require eculizumab therapy. The best candidates for treatment are those with a large PNH clone associated with disabling fatigue, thromboses, transfusion dependence, frequent pain paroxysms, renal insufficiency, or other end-organ complications from disease. Watchful waiting is appropriate for asymptomatic patients and for those with mild symptoms. In patients with hypoplastic PNH, therapy should be directed toward the underlying BM failure with careful monitoring of the PNH clone using flow cytometry. Patients who meet criteria for severe aplastic anemia should be managed with either allogeneic BMT or immunosuppressive therapy depending on the age of the patient and the availability of a suitable donor.

Monitoring Patients on Eculizumab

Most patients notice symptomatic improvement within hours to days after the first dose of eculizumab. Patients should be monitored with a complete blood count, reticulocyte count, LDH level, and biochemical profile weekly for the first 4 weeks and then at least monthly thereafter. The LDH level usually returns to normal or near normal within days to weeks after starting eculizumab; however, the reticulocyte count usually remains elevated, and the hemoglobin response is highly variable. The reticulocyte count often remains elevated because most PNH patients taking eculizumab continue to have extravascular hemolysis. Erythrocytes of PNH patients taking eculizumab have increased deposition of C3 because of CD55 deficiency, and these cells are prematurely removed by the spleen.[4,24] The hemoglobin response largely depends on the degree of extravascular hemolysis and the amount of underlying BM failure. In classical PNH patients who are transfusion dependent, a marked decrease in RBC transfusions is observed in virtually all patients, with more than 50% achieving transfusion independence. Breakthrough intravascular hemolysis and a return of PNH symptoms occurs in fewer than 5% of PNH patients treated with eculizumab. This typically occurs 1 or 2 days before the next scheduled dose and is accompanied a spike in the LDH level. If this occurs on a regular basis, the interval between dosing can be shortened to 12 or 13 days or the dose of eculizumab can be increased to 1200 mg every 14 days. It is also important to recognize that increased complement activation that accompanies infections (e.g., influenza or viral gastroenteritis) or trauma can also result in transient breakthrough hemolysis. These single episodes of breakthrough hemolysis do not require a change in dosing. Patients with continued anemia, a normal or near normal LDH level, and a robust reticulocyte count are likely to be having substantial extravascular hemolysis. In this setting, a direct antiglobulin test will likely be positive for complement and negative for immunoglobulin G.

Thrombosis

Thrombosis is often the most pernicious complication of PNH and is an indication for eculizumab and anticoagulation. In patients with acute onset of abdominal vein thrombosis, thrombolytic therapy has been successfully used. However, in some patients, thrombolytic therapy and anticoagulation are relatively contraindicated because of severe thrombocytopenia. Terminal complement blockade appears to be the most effective way to prevent further thrombotic events and in some patients may allow for the discontinuation of anticoagulation.[25-27] Pregnancy, surgery, or the use of oral contraceptives can increase the risk for thrombosis in PNH and should be considered high risk.

Bone Marrow Transplantation

Bone marrow transplantation is the only curative therapy for PNH, but it is associated with significant morbidity and mortality. The International Bone Marrow Transplant Registry (IBMTR) reported a 2-year survival probability of 56% in 48 recipients of HLA-identical sibling transplants between 1978 and 1995. The median age was 28 years. The majority of the deaths in this study occurred within 1 year of transplantation. One of seven recipients of alternative donor allogeneic transplants reported to the IBMTR during this period was alive 5 years after transplant. The European Blood and Marrow Transplant group reported a 5-year survival rate of 70% after allogeneic BMT for PNH; however, only 54% met criteria for classical PNH. The median age in the study was 30 years. Graft failure occurred in 6% of patients, and acute and chronic graft-versus-host disease (GVHD) occurred in 15% and 20% of patients, respectively.

More recently, the Gruppo Italiano Trapianto Midollo Osseo (GITMO), published a retrospective study of 26 patients (median age, 32 years) who received BMT for PNH in Italy between 1988 and 2006.[28] HLA-matched sibling donors were used as stem cell sources for 22 patients; one patient received stem cells from a matched unrelated donor, and three received stem cells from mismatched donors (two related and one unrelated). A myeloablative conditioning regimen (busulfan + cyclophosphamide) was used for 15 of the patients. The remaining 11 received a variety of different reduced intensity conditioning regimens, most being cyclophosphamide or fludaribine based. GVHD prophylaxis was highly variable but largely cyclosporine based. The 10-year probability of survival was 57% for all patients, with a median follow-up of 131 months. There was one primary graft failure in a patient receiving a myeloablative conditioning regimen and one secondary graft failure in a patient who received a nonmyeloablative BMT; both patients eventually died from complications of a second BMT. Acute GVHD (aGVHD) greater than stage 2 occurred in three of the 26 patients; chronic GVHD (cGVHD) occurred in 10 of 20 evaluable patients with four (16%) experiencing extensive cGVHD. The transplant related mortality at 1 year was 26% in patients receiving a myeloablative conditioning regimen and 63% in the group that received a nonmyeloablative regimen; however, this was likely because all three patients in the nonmyeloablative group received a BMT from a non-identical donor. There was just one patient in the myeloablative group who received a BMT from an unrelated or mismatched donor.

In summary, BMT should not be offered as initial therapy for most patients with classical PNH given the high morbidity and mortality, especially when using unrelated or mismatched donors. Exceptions are PNH patients in countries where eculizumab is not available and patients who do not have a good response to eculizumab therapy. Patients with hypoplastic PNH and life-threatening cytopenias continue to be reasonable candidates for BMT. A myeloablative conditioning regimen is not required to eradicate the PNH clone. Allogeneic BMT after a nonmyeloablative conditioning regimen can cure PNH. Whether or not there is an advantage to one approach over the other will require further study; however, nonmyeloablative regimens may be preferable in young patients seeking to maintain fertility and patients with moderate organ dysfunction who may not

tolerate a myeloablative regimen. Last, because BMT is the only curative therapy available for PNH, continued use and investigation of this approach in selected patients is reasonable.[29] Recent advances in mitigating GVHD such as posttransplant high-dose cyclophosphamide may particularly effective in PNH, but further studies are required.[30]

APPROACH TO TREATMENT

The author finds it useful to classify PNH patients as either "classical" or "hypoplastic." This can usually be accomplished by ordering a complete blood count; reticulocyte count; LDH level; peripheral blood flow cytometry for PNH; and BM aspirate, biopsy, and cytogenetics. Patients with classical PNH tend to have mild to moderate cytopenias, a normocellular to hypercellular BM, an elevated reticulocyte count, a markedly elevated LDH level, and a relatively large PNH granulocyte population (>30%). In contrast, hypoplastic PNH patients present with manifestations similar to that of aplastic anemia or hypoplastic MDS. These patients typically present with moderate to severe cytopenias, a hypocellular BM (<25% cellularity), a decreased corrected reticulocyte count, a normal or mildly elevated LDH level, and a relatively small (<20%) PNH granulocyte population. Most, but not all, patients can be readily subdivided into classical versus hypoplastic PNH, a distinction that aids with therapeutic decisions. See Red Box on Approach to Diagnosing Paroxysmal Nocturnal Hemoglobinuria.

Hypoplastic Paroxysmal Nocturnal Hemoglobinuria

Because BM failure is the major risk for patients with hypoplastic PNH, I direct my therapy toward the pancytopenia. If, in addition to the PNH, the patient fulfills criteria for severe aplastic anemia (see Chapter 28), appropriate therapeutic options include allogeneic BMT, high-dose cyclophosphamide, or ATG and cyclosporine. Young patients (i.e., <30 years of age) with an HLA-matched sibling should be transplanted; for older patients and for those without an HLA-matched sibling, high-dose cyclophosphamide or antithymocyte and cyclosporine is appropriate. The author prefers to use high-dose cyclophosphamide because of the improved quality and duration of remissions. If the patient's cytopenias do not fulfill criteria for severe aplastic anemia, supportive care or a trial of immunosuppressive therapy is appropriate.

Classical Paroxysmal Nocturnal Hemoglobinuria

Symptoms in patients with classical PNH vary from mild, to severely debilitating, to acutely life threatening. Hence, therapy should be directed toward the specific manifestations (e.g., anemia, thrombosis). Allogeneic BMT, preferably from an HLA-matched sibling, is appropriate for patients with severely debilitating or acutely life-threatening disease. In general, these are patients with recurrent thrombosis or those with clonal evolution to either MDS or acute leukemia. Patients with less severe disease should not be transplanted because of the relatively high morbidity and mortality of the procedure. ATG and cyclosporine or high-dose cyclophosphamide does not appear to benefit patients with classical PNH.

Anemia

All patients with classical PNH should be prescribed folic acid (1-2 mg/day). Patients with absent iron stores, usually because of chronic intravascular hemolysis, should be treated with oral iron supplementation. Eculizumab has become the standard of care to treat selected patients with classical PNH. It is the only drug demonstrated in a randomized study to benefit PNH patients. Eculizumab has been shown to decrease the need for transfusions, decrease paroxysms, and improve quality of life in patients with classical PNH; however, it has not been shown to benefit patients with hypoplastic PNH. In classical PNH, the author recommends eculizumab for patients with disabling fatigue, thromboses, transfusion dependence, frequent pain paroxysms, renal insufficiency, or other end-organ complications from disease. Watchful waiting is appropriate for asymptomatic patients and those with mild symptoms.

If eculizumab is unavailable, a trial of prednisone (0.5-1.0 mg/day) can occasionally decrease hemolysis and increase hemoglobin levels. If a salutary effect is not achieved within 6 to 8 weeks, the steroids should be discontinued. In responding patients, the steroids should be tapered to the lowest dose that still provides a beneficial effect. Alternate-day steroids can help decrease the risk of deleterious long-term side effects. Danazol (400 mg/day) can also decrease hemolysis; if no response is observed after 8 weeks, the drug should be discontinued.

Thrombosis

Patients who present with acute life-threatening or organ-threatening thrombosis should be considered for thrombolytic therapy followed

Approach to Diagnosing Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) has an estimated incidence of 2 to 5 per million in the United States. This, coupled with its protean manifestations, makes diagnosing PNH a challenge for even the most astute diagnostician. However, given the ease and specificity of modern diagnostic assays, the most important attribute a physician can possess in diagnosing PNH is to maintain a high level of suspicion and to be cognizant of the various presentations of the disease. A small sample of peripheral blood sent to an experienced flow cytometric laboratory is usually sufficient to establish or exclude the diagnosis of PNH. These assays are fast, reliable, and inexpensive. If monoclonal antibodies are used to establish the diagnosis, it is imperative that two or more antibodies be used on at least two different lineages. Assaying granulocytes is the most reliable method of diagnosing PNH because they are not affected by blood transfusions. The author prefers to use FLAER over monoclonal antibodies on granulocytes and monocytes because of the improved sensitivity and specificity; anti-CD59 is the most reliable marker on erythrocytes.

Classical PNH is usually more conspicuous than hypoplastic PNH. Patients typically present with direct antiglobulin-negative hemolytic anemia, hemoglobinuria, and mild to moderate cytopenias. Obscure paroxysms of back pain, abdominal pain, fatigue, or headaches are often present. The BM is typically normocellular to mildly hypercellular with intense erythroid hyperplasia and mild to moderate dyserythropoiesis. BM iron stores are frequently, but not always, absent. PNH patients can also present with abrupt, severe abdominal pain and jaundice caused by thrombosis. All patients presenting with unexplained hepatic vein, portal vein, mesenteric vein, or portal vein thrombosis should be screened for PNH.

It is important to distinguish PNH from myelodysplastic syndrome. Most patients with refractory anemia should be screened for PNH, especially those with moderate to severe cytopenias, an elevated lactate dehydrogenase level, and a hypocellular BM. In addition, all patients diagnosed with aplastic anemia should be screened for PNH. As few as 3% PNH erythrocytes may result in an elevated LDH. In rare instances, idiopathic myelofibrosis or autoimmune hemolytic anemias can mimic PNH. Patients with a history of aplastic anemia—especially those managed with immunosuppressive therapy—should be monitored closely for the outgrowth of PNH.

by long-term anticoagulation. Thrombosis is probably the most compelling reason to start eculizumab in PNH patients. Whether or not anticoagulation can be safely discontinued after eculizumab induction is still unknown, but patients who respond well to eculizumab therapy may not need long-term anticoagulation.

CHAPTER 30

ACQUIRED DISORDERS OF RED CELL, WHITE CELL, AND PLATELET PRODUCTION

Jaroslaw P. Maciejewski and Ramon V. Tiu

ACQUIRED PURE RED CELL APLASIA

Acquired pure red cell aplasia (PRCA) is characterized by the presence of an acquired severe normochromic, most frequently normocytic, anemia associated with a complete disappearance of reticulocytes and erythroid precursors in the marrow and normal production of myeloid cells and platelets. Consequently it is presumed that the defect lies within erythroid precursors and not within stem cells as seen in aplastic anemia. Initially described by Kaznelson[1] in 1922, PRCA is a rare bone marrow failure disorder without geographic or racial predilection. All ages can be affected, but, if present in children, it is called transient erythroblastopenia of childhood (TEC) and may be difficult to distinguish from congenital causes of anemia, mainly Diamond-Blackfan anemia (DBA). Former nosology included various terms such as *erythrophthisis, chronic hypoplastic anemia, pure red cell agenesis,* and *primary red cell anemia.*

ETIOLOGY AND CLASSIFICATION

Acquired forms of PRCA must be distinguished from congenital forms of PRCA, which usually manifest themselves early in life (see Chapter 28). Acquired PRCA occurring in childhood may be difficult to distinguish from DBA. As an acquired disease, PRCA may be a primary disorder or secondary to a variety of systemic diseases, including a number of hematologic diseases (Table 30-1).

Pathogenesis

The inciting events in the development of PRCA are not known. However, as with idiopathic aplastic anemia, viruses or exposure to chemicals can serve as potential triggers (Fig. 30-1). Theoretically a viral infection could lead to depletion of erythroid precursors. Studies of B19 parvovirus (see later) suggest such an etiology. Because hematopoietic stem cells are not affected by B19 parvovirus, myeloid cells and platelets are normally produced, and upon clearance of the virus, normal erythroid production can resume. Similarly, in immune-mediated PRCA, the mechanism of erythroid inhibition may vary and may include (1) antibodies to proteins specific to erythroblasts, (2) direct cytotoxic T lymphocyte (CTL)–mediated killing of erythroid precursors, and (3) production of soluble products by CTLs such as inhibitory or proapoptotic cytokines that directly affect the erythroid series.

Historically, initial studies concentrated on examining the effects of soluble serum inhibitors of erythropoiesis. These investigations revealed a decline in erythroid colony formation in the presence of patient serum or failure to induce erythroid colony formation in the presence of erythropoietin.[2,3] Such serum inhibitors can be found in 40% of patients with PRCA.[2-4] In 60% of patients, erythroid colony formation can be induced in vitro with hematopoietic growth factors.[2-4] The inhibitory activity is localized to the immunoglobulin (Ig) G fraction and disappears upon achieving a clinical remission. The antigenic targets for autoantibodies have not been well characterized, but various stages of erythroid differentiation can be affected (also called PRCA type A), as seen in the reduction of burst-forming unit–erythroid (BFU-E) or colony-forming unit–erythroid (CFU-E).[5,6] In certain cases of antibody-mediated PRCA, the involvement of the complement system is a prerequisite to disease causation.[7] Perhaps the exception and a model for antibody-induced red cell aplasia is the identification of PRCA associated with antierythropoietin antibodies (also called PRCA type B) in rare cases.[8,9] Consistent with the specificity of the antibodies, myeloid colony formation is not impaired, making it unlikely that a more ubiquitous inhibitory cytokine mediates the specific erythroid inhibition.

In recent years, experimental and clinical observations have suggested that PRCA may be mediated by CTLs, which specifically recognize and kill erythroid precursors similar to CTL-mediated killing of cells in aplastic anemia.[10-12] Although such a T cell–mediated antierythroid response is likely to be polyclonal, rare instances of T-cell large granular lymphocyte (T-LGL) leukemia associated with PRCA or erythroid inhibition may represent an extreme form of the clonal continuum of CTL responses (see T-Cell Large Granular Lymphocyte–Associated PRCA). In addition to CTLs expressing α/β T-cell receptors (TCRs), T cells with a γ/δ TCR can mediate PRCA.[13,14] The antigens/antigenic peptides triggering such a response have not been well described.[15,16] Similarly, natural killer (NK) cells have also been implicated in mediating cytotoxicity directed against erythroid precursors.[17,18] NK cells, like γ/γ T lymphocytes and unlike α/β CTLs, do not rely on major histocompatibility complex (MHC)–restricted cytotoxicity, but may use killer-cell immunoglobulin-like receptors (KIRs).[19,20] KIRs inhibit cytolysis when they encounter a cell bearing human leukocyte antigen (HLA) class I molecules. A lack of appropriate KIRs may predispose cells to increased attack by NK cells or γ/δ CTLs. Physiologic downregulation of KIRs has been implicated in the pathogenesis of PRCA in a patient with concomitant γ/δ T-LGL clonal proliferation.[13,21] An alternative NK-cell cytotoxic mechanism independent of KIR has been reported in healthy individuals.[22]

Peripheral T-helper lymphocyte polarization has been implicated in the pathogenesis of PRCA.[16,23] Polarization toward the Th2 functional subtype (interleukin [IL]-4) during disease relapse and normalization of Th1/Th2 ratio after effective treatment has been reported in both monoclonal gammopathy of undetermined significance (MGUS) and thymoma-associated PRCA. Further studies have shown increased C-MAF gene expression in relapsed PRCA associated with Th2 polarization, a mechanism that may help explain the alteration in Th1/Th2 balance.[16]

PRIMARY PURE RED CELL APLASIA

Primary PRCA occurs in the absence of any underlying disorder. It may be acute and self-limited or may be a chronic and refractory condition. Acute forms are uncommon. Most cases are protracted and chronic, unlike TEC, which is an acute and self-limited disorder. Most of the cases of classic primary PRCA are autoimmune in origin, but a significant proportion will remain idiopathic in origin in spite of an exhaustive workup.

Table 30-1 Classification of Pure Red Cell Aplasia

Congenital (DBA)		
Primary	Autoimmune Idiopathic	
Secondary	Thymoma[8,9,32-34] Hematologic malignancies	CLL[24,25] T-LGL/chronic NK-LGL leukemia[10,11,17,18,28-31] Myeloma[593] NHL[594,595] MDS[596] ALL[597-599]
	Solid tumors	Renal cell carcinoma[600] Thyroid cancer[601] Various adenocarcinomas[602,603]
	Infections	Parvovirus B19[50] EBV,[39] mumps HIV,[61] HTLV-1[28] CMV[60] Viral hepatitis (hepatitis A,[55,56,604] hepatitis B[57,58]) Leishmaniasis[244] Gram-positive systemic infections (e.g., staphylococcemia) Meningococcemia
	Autoimmune conditions	SLE[74] RA[69] Sjögren syndrome[71,72] Mixed connective tissue disease[66] Autoimmune hepatitis[605] Anti-EPO antibodies[606,607] ABO-incompatible BMT Minor incompatibility[93-98]
	Drugs and chemicals	
	Pregnancy[43,44]	
	Severe nutritional deficiencies[608,609]	
	Renal failure[610]	

ALL, Acute lymphoblastic leukemia; *BMT,* bone marrow transplantation; *CLL,* chronic lymphocytic leukemia; *CMV,* cytomegalovirus; *DBA,* Diamond-Blackfan anemia; *EBV,* Epstein-Barr virus; *EPO,* erythropoietin; *HIV,* human immunodeficiency virus; *HTLV-1,* human T-lymphotrophic virus-1; *MDS,* myelodysplastic syndrome; *NHL,* non-Hodgkin lymphoma; *NK-LGL,* natural killer large granular lymphocyte; *RA,* refractory anemia; *SLE,* systemic lupus erythematosus; *T-LGL,* T-cell large granular lymphocyte.

SECONDARY FORMS OF PURE RED CELL APLASIA

Clinical Associations

B-Cell Chronic Lymphocytic Leukemia–Associated PRCA

In B-cell chronic lymphocytic leukemia (CLL), PRCA can be observed in up to 6% of cases.[10,24,25] The underlying pathogenetic mechanisms are not clear, and the inhibition of the erythroid series does not appear to be mediated by a soluble factor.[26,27] The distinction between whether the PRCA is a result of the primary B-cell CLL disease or its therapy becomes difficult in circumstances when PRCA presents as a late event. In most cases, PRCA cannot be attributed simply to infiltration of the marrow by the lymphoma.

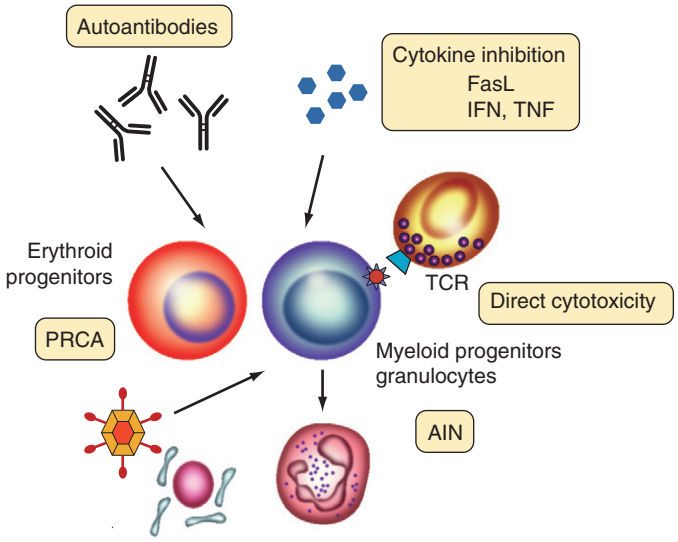

Figure 30-1 PATHOGENESIS OF PURE RED CELL APLASIA. *AIN,* Autoimmune neutropenia; *FasL,* Fas ligand; *IFN,* interferon; *PRCA,* pure red cell aplasia; *TCR,* T-cell receptor; *TNF,* tumor necrosis factor.

T-Cell Large Granular Lymphocyte–Associated PRCA

Although neutropenia is a typical finding in T-LGL leukemia, PRCA with varying degrees of erythroblastopenia can also be observed in 10% to 15% of patients with T-LGL leukemia.[11,28-31] In such a setting, PRCA is often accompanied by red cells with an increased mean corpuscular volume. T-LGL leukemia with PRCA may respond to oral cyclophosphamide, cyclosporine A (CsA), methotrexate, and in refractory cases to antithymocyte globulin (ATG) therapy. It is possible that PRCA associated with T-LGL leukemia represents an extreme form of the T cell–mediated disease that, if polyclonal, might be classified as idiopathic PRCA.

Thymoma-Associated PRCA

Thymoma is associated with PRCA; thus a chest x-ray examination or computed tomographic (CT) scan should be included in the workup for PRCA. Antibodies with direct inhibitory effects against erythroid precursors may be present.[8,9,32-34] T cell–mediated inhibition of erythropoiesis has also been implicated in the pathogenesis of PRCA associated with either benign or malignant thymomas.[35-38] Thymectomy is the usual initial treatment approach[34]; however, incomplete responders, nonresponders, and patients who relapse are common,[38] necessitating additional therapies in the form of azathioprine,[39] intravenous immunoglobulins (IVIgs),[40] and CsA.[41]

Pregnancy-Associated PRCA

Pregnancy-associated PRCA is a self-limited syndrome that may occur at any age of gestation.[42] It has a high risk for relapse during subsequent pregnancies and can be safely managed with either blood transfusions or corticosteroids.[43,44] Patients with other forms of PRCA may also be more prone to relapse during pregnancy.[45]

Parvovirus B19 and Other Viral-Induced PRCAs

Parvovirus B19 is a single-stranded deoxyribonucleic acid (DNA) virus, which in normal individuals causes fifth disease (erythema infectiosum) in children and arthropathy in adults.[46-49] The cellular

receptor for the virus is the P antigen, a blood group antigen also responsible for the agglutination reaction that occurs in the presence of the virus. Detection of parvovirus B19–specific IgM without anti–parvovirus B19 IgG supports the diagnosis of acute infection, whereas the parvovirus B19–specific IgG suggests immunity.[50] Addition of parvovirus B19 in vitro to cultures of erythroid progenitor cells completely abolishes erythroid colony formation.[47,48] Primary infection causes lifelong immunity; however, it is possible that a latent virus may persist in a healthy individual for years.

A transient aplastic crisis is a typical complication of a primary parvovirus B19 infection in patients with increased red cell turnover (usually chronic hemolysis, e.g., hemoglobinopathies, and hereditary disorders of red blood cell [RBC] membrane, e.g., hereditary spherocytosis).[51-53] In typical cases, the occurrence of acute reticulocytopenia results in a sudden drop in hemoglobin (Hb)/hematocrit (Hct) levels as RBC destruction continues but is unsupported by a suppressed marrow. Occasionally, characteristic giant pronormoblasts may be seen in marrow aspirates (Fig. 30-2). This disorder is often self-limiting with the evolution of a protective IgG response. Viral titers in the serum of affected patients may be high. Supportive transfusions may be needed during the acute phase of the disease.

A more chronic form, parvovirus B19–related PRCA, may develop in immunocompromised patients as, for example, in acquired immunodeficiency syndrome (AIDS). In such cases, IVIg can produce remarkable responses. High doses of IVIg are required (>2 g/kg) because an insufficient dose may not produce the desired effect. DNA dot blot hybridization is the best diagnostic test for the detection of viremia. Parvovirus B19 can also be detected by polymerase chain reaction (PCR), a routinely available test, but this method may provide a high rate of false-positive results. However, if test results are negative, it excludes B19 parvovirus–mediated disease.[50] Improved tests have been developed that allow for the detection of neutralizing antibodies and infectivity of parvovirus B19.[54]

Several other viral infections, including viral hepatitis (A[55,56] and C[57,58]), Epstein-Barr virus (EBV),[59] cytomegalovirus (CMV),[60] human T-lymphotrophic virus-1 (HTLV-1),[28] and human immunodeficiency virus (HIV)[61] have been implicated as causative agents of PRCA. Little is known about the exact mechanisms underlying these disorders, but they likely involve T cell–mediated suppression as observed during HTLV-1 infection[28] and EBV or antibody-mediated destruction of red cell precursors, as in hepatitis C–induced PRCA.[57,58] Frequently the presence of multiple comorbidities and medications makes it difficult to pinpoint the exact causative agent.[61,62]

Connective Tissue Disease–-Associated PRCA

The majority of connective tissue diseases associated with PRCA are autoimmune in nature. Several rheumatologic diseases have been associated with PRCA, including adult-onset Still disease,[63,64] dermatomyositis,[65] mixed connective tissue disease,[66] polymyositis,[67] rheumatoid arthritis,[68,69] Sjögren syndrome,[70-72] and systemic lupus erythematosus.[73-75] The pathogenesis of the PRCA in this setting may vary and includes autoantibody-mediated erythroid inhibition,[76] autoantibody directed against erythropoietin,[77] and CTL-mediated killing of erythroid precursors.[73]

Drug-Induced PRCA

Various chemical agents and drugs have been associated with PRCA. The mechanisms responsible for erythroid inhibition may be diverse depending on the offending agent (Table 30-2) but may include induction of antibodies targeting the drugs or drugs bound to cellular and plasma proteins. Another possible mechanism involves drug-mediated triggering of T-cell responses, or direct toxicity to the erythroid series as seen with diphenylhydantoin.[78]

Erythropoietin Antibody–Associated PRCA

Erythropoietin is produced mainly by the kidneys and to a limited extent by the liver. Recombinant erythropoietin is used in the treatment of anemias of various origins, including, for example, anemia of chronic disease, renal disease, and a variety of bone marrow failure syndromes, particularly myelodysplastic syndrome (MDS). Cases of PRCA have developed as a consequence of antibody formation

Table 30-2 Drugs and Chemicals Implicated in Pure Red Cell Aplasia

Alemtuzumab[152]	Isoniazid[631-633]

against endogenous erythropoietin[79] or while receiving treatment with recombinant erythropoietin.[80-82] The latter condition has been referred to as *epoetin-induced PRCA* or *EPO-PRCA.* The first three cases of EPO-PRCA were reported between 1988 and 1998,[81,83] with 13 cases subsequently reported in France between 1998 and 2000, mainly related to exposure to epoetin alpha (Eprex; 92%) and epoetin beta (NeoRecormon; 8%).[82] The exact pathogenesis remains unclear but may be related to the formation of neutralizing antierythropoietin antibodies. There are several risk factors to the development of EPO-PRCA, including subcutaneous route of administration, use of epoetin alpha stabilized in a human serum albumin (HSA)–free formulation, use of silicone oil as lubricant in prefilled Eprex syringes, and use in patients with chronic renal disease.[84,85] All these factors increase the immunogenic potential of the antierythropoietin antibodies. This observation has lead to modification in the storage, handling, and administration of Eprex favoring intravenous (IV) administration, especially with Eprex stabilized with HSA-free formulation, and avoidance of the subcutaneous non–HSA stabilized Eprex for patients with chronic renal disease. Of note is that cases of EPO-PRCA occurring after IV epoetin administration have been described.[80,86] There are reports of human erythropoietin (HuEPO) neutralizing antibody PRCA related to the use of biosimilar recombinant HuEPO in Thailand.[87] Diagnostic criteria have also been proposed incorporating major features (treatment with epoetin for at least 3 weeks, decrease in Hgb by 0.1 g/dL/day without transfusions or transfusion need of about 1 unit/week to keep hemoglobin level stable, reticulocyte count $<10 \times 10^9$/L, no major drop in white blood cell [WBC] and platelet counts), minor features (skin and systemic allergic reactions), and accessory investigations (e.g., bone marrow showing normal cellularity and <5% erythroblasts with evidence of maturation block, and serum assay showing presence of antierythropoietin antibodies and evidence of neutralizing capacity).[80] All major criteria are required for diagnosis, whereas minor features must be confirmed by additional confirmatory tests, usually in the form of bone marrow biopsy and detection of neutralizing antierythropoietin antibodies. The most commonly used tests to detect antibodies are enzyme-linked immunosorbent assay (ELISA), radioimmunoprecipitation assay, and surface plasmon resonance. Once antibodies are detected, their neutralizing ability is tested using an in vitro bioassay. Following establishment of diagnosis, management should include discontinuation of exogenous erythropoietin, administration of immunosuppressive agents, or, in cases of anemia secondary to renal insufficiency, renal transplantation. It is possible to use and regain response to recombinant erythropoietin once antierythropoietin antibodies have disappeared.[88]

PRCA Postallogeneic Stem Cell Transplantation

In contrast to HLA matching, ABO blood group incompatibility plays a minor role in the success of allogeneic hematopoietic stem cell transplantation (HSCT). However, PRCA may be associated with major ABO incompatibility between the donor and recipient, leading to inhibition of donor erythroid precursors by residual host isoagglutinins. This complication is more commonly observed following the use of nonmyeloablative conditioning regimens. PRCA may also be resistant to the withdrawal or decrease of immunosuppression, or donor lymphocyte infusions. Responses to rituximab,[89,90] erythropoietin,[91] and azathioprine[91] have been reported. A case responsive to purified $CD34^+$ cell infusion has also been reported.[92] Resolution of PRCA is generally associated with decrease and subsequent disappearance of host isoagglutinins.[93-98]

PRCA Postradiation Therapy

In rare circumstances, PRCA may be associated with prior radiation therapy. The cases described usually involve radiation therapy being administered to a patient with an underlying thymoma not previously associated with PRCA.[99,100]

PRCA Associated With Immune Dysregulation, Polyendocrinopathy, Enteropathy, X-Linked Syndrome

Immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome is a rare X-linked recessive condition typically seen during infancy. Clinical features may include type 1 diabetes mellitus, eczema, and autoimmune hepatitis. PRCA not associated with parvovirus infections develops at around 39 months of life and is responsive to steroid therapy.[101]

Anemia is the leading symptom of PRCA and can be severe at diagnosis because the fall in hemoglobin occurs over a protracted period of time and patients often exhibit a good degree of adaptation. Arrest of erythropoiesis is obvious with a profound reticulocytopenia. In children, TEC is usually diagnosed during evaluation of a febrile illness. In primary, idiopathic PRCA, physical signs other than those of anemia are usually absent. In secondary PRCA, the physical findings are consistent with the underlying primary disease.

LABORATORY EVALUATION

A complete blood cell count (CBC) with differential, peripheral smear review, reticulocyte count, and a bone marrow examination remain the cornerstone in the diagnosis of PRCA. The classic hematologic picture of PRCA includes a CBC showing a normocytic, normochromic anemia (anemia associated with T-LGL leukemia is often macrocytic) with normal WBC and platelet count. The reticulocyte count is significantly reduced to less than 1% (a reticulocyte level greater than 2% is not compatible with the diagnosis of PRCA; (Fig. 30-3). The bone marrow examination generally shows absence of the erythroid lineage and normal appearance of granulocytic and monocytic precursors and megakaryocytes. Erythroid precursors, if present, are usually less than 1%, and only a few residual proerythroblasts or basophilic erythroblasts may be seen. Blast cell numbers and cellularity are within normal limits. There are no dysplastic changes, ringed sideroblasts, or reticulin fibrosis. Cytogenetic evaluation is normal. In some cases, neutropenia,[102] mild thrombocytopenia, eosinophilia,[16] thrombocytosis,[16] leukocytosis, or relative lymphocytosis may be seen. Cytogenetic abnormalities, if present, may indicate concomitant myelodysplasia and is a poor prognostic marker for both response to treatment and propensity to leukemic

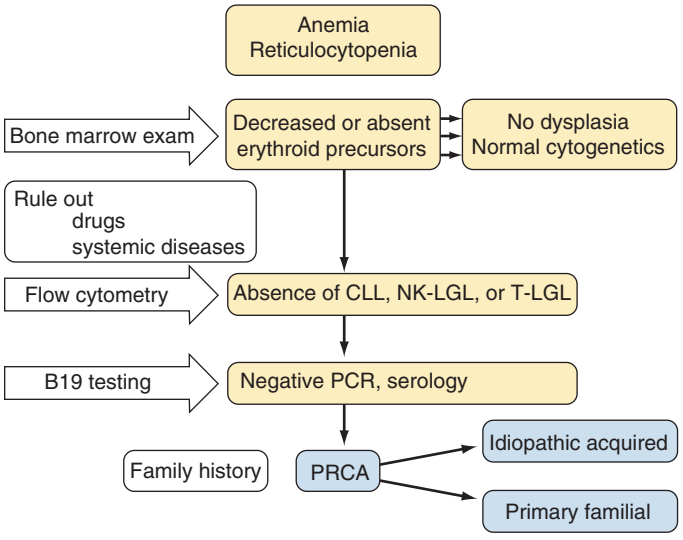

Figure 30-3 DIAGNOSTIC ALGORITHM IN PURE RED CELL APLASIA. *CLL,* Chronic lymphocytic leukemia; *NK-LGL,* natural killer large granular lymphocyte; *PCR,* polymerase chain reaction; *PRCA,* pure red cell aplasia; *T-LGL,* T-cell large granular lymphocyte.

transformation.[103,104] During the natural history of PRCA, ineffective erythropoiesis characterized by maturation arrest at the proerythroblast or basophilic erythroblast stage may be observed and signifies either partial response to treatment or initial recovery from treatment or a prelude to the development of full-blown PRCA.[105]

It is important to exclude vitamin B_{12} and folate deficiencies, and depending on the etiology and associated disease, other blood and bone marrow findings may be seen. The presence of giant and vacuolated pronormoblasts in the bone marrow examination should raise the suspicion for parvovirus B19 infection.[50] The presence of large granular lymphocytosis, neutropenia, and/or thrombocytopenia, expansion of $CD3^+CD8^+CD57^+$ T cells, clonal cytotoxic TCR gene rearrangement, expansion of specific TCR Vβ region family gene segment, and splenomegaly may point toward concomitant T-LGL leukemia,[106,107] B-cell lymphocytosis, especially of the $CD5^+/CD19^+/CD20^+/CD23^+$/cyclin $D^-/SmIg^{-dim}$ phenotype with concomitant lymphadenopathy, hepatosplenomegaly, hypogammaglobulinemia, and thrombocytopenia may be very suggestive of a B-cell CLL. Another laboratory finding that may help point to a secondary cause of PRCA includes the presence of monoclonal gammopathy.[16] Parvovirus B19 DNA titers (DNA hybridization and amplification techniques) may show high levels of the virus at 10^{12} genome copies per milliliter, but it is important to note that serologic (IgM and IgG) titers are usually absent.[50] Erythropoietin antibodies,[82] antinuclear antibodies,[108,109] and/or complement consumption may point toward a specific disease mechanism.[110] A radiographic workup may also be useful in the clinical workup because chest x-ray examination or CT scan may show evidence of a thymoma.

DIFFERENTIAL DIAGNOSIS

PRCA can be easily differentiated from aplastic anemia and other types of bone marrow failure syndromes. A distinction between MDS with erythroid hypoplasia and idiopathic PRCA may be more difficult. In childhood, TEC has to be distinguished from DBA, but a history of normal blood counts, late onset of manifestation, and transient disease course are characteristic of TEC.

THERAPY

The distinction between primary and secondary forms of PRCA is essential because many secondary types have specific and very effective therapies (Table 30-3). All potentially offending drugs should be discontinued, and drug-associated PRCA should remit within 3 to 4 weeks. Nutritional deficiencies (B_{12} and folic acid) should be excluded and treated if present. The therapy of primary and secondary forms of PRCA refractory to the treatment of an underlying disease may be challenging and should include a sequential trial of various immunosuppressive agents until a response is achieved. Spontaneous remissions have been reported.

Surgery or Radiation

In cases associated with thymoma, thymectomy is the usual initial treatment of choice before immunosuppression and may induce remission with return of erythropoiesis in 4 to 8 weeks in about 30% to 40% of patients.[111-113] Patients who remain refractory following surgery should be treated as patients with idiopathic PRCA. The removal of a thymoma may improve responsiveness to immunosuppressive therapy.[112] Thymectomy in the absence of a thymoma in other forms of PRCA is not recommended. In circumstances where surgical resection of thymoma is contraindicated, radiation therapy with or without chemotherapy may be administered.[114]

Medical

Supportive

Supportive care includes blood transfusions and iron chelation with deferasirox (Exjade). Deferasirox is a new once-daily, oral iron chelator developed for treating transfusional iron overload syndromes used in a variety of hematologic disorders, including thalassemia and sickle cell anemia; it works primarily by promoting fecal excretion of iron. Side effects may include diarrhea, renal failure, and rarely agranulocytosis.[115,116]

Immunosuppression

Prednisone therapy at a dose of 0.5 to 1 mg/kg is associated with significant response rates (approximately 40%) and should constitute the initial therapeutic approach.[104] Initial responses are generally observed after 4 to 6 weeks.[103,117] A slow taper of prednisone is suggested over a period of 3 to 4 months. The disease may relapse, and the minimal maintenance dose of corticosteroids may need to be established to maintain the desired hemoglobin levels.[118] Trials of prednisone therapy without clinical response longer than 8 weeks are not warranted.[103,104,117]

Alternative therapies may include cyclosporine, oral cyclophosphamide, azathioprine, antithymocyte globulin (ATG), rituximab, and alemtuzumab (see Table 30-3). Erythropoietin and darbepoietin[119,120] are usually not effective as a sole agent but may hasten recovery following an adequate trial of cyclophosphamide. No randomized trials exist to favor a particular treatment based on efficacy.

Table 30-3 Therapy for Pure Red Cell Aplasia and Its Results

	Study								
Agent	*Chikkappa*[143]	*Means*[145]	*Au*[153]	*Dessypris*[117]	*Zecca*[655]	*Lacy*[104]	*Charles*[103]	*Sloand*[149]	*Abkowitz*[147]
Steroids				18/41		9/29	9/36	—

Daclizumab (Zenapax)								6/15	
Rituximab					1/1				
Alemtuzumab (Campath)			2/2						
Methotrexate							2/37		

The choice of therapy may be influenced by clinical clues. For example, the presence of large granular lymphocytes (LGLs) may suggest the use of CsA, hypogammaglobulinemia may be corrected with IVIg, whereas detection of hypergammaglobulinemia or monoclonal protein may suggest a choice of rituximab. Most refractory cases may require administration of ATG. The age of the patient may influence the choice of the cytotoxic agent, which may pose a significant risk for the development of secondary leukemias, especially with a prolonged administration.

Danazol is a synthetic attenuated androgen that has been used for many years for the treatment of a variety of hematologic disorders, mainly myelofibrosis.[121] Usually given at 200 mg orally (PO) twice a day, the maximum dose per day is 600 mg. It has been used to treat PRCA either as a single agent or in conjunction with steroids or other agents and has shown efficacy in PRCA of various etiologies.[122-125] The main adverse events reported include liver transaminitis and vascular liver tumors.

IVIg (Gammagard, Octagam, Panglobulin) given at 1 to 2 g/kg IV for 5 days is also effective in several types of PRCA.[126-129] Higher doses of usually 2 g/kg of IVIg for 5 days are necessary for the treatment of parvovirus B19 virus–induced PRCA. In AIDS patients with parvovirus B19 virus–induced PRCA, a regimen consists of induction therapy with 1 g/kg daily for 1 to 2 days followed by 1 g/kg for 2 days. If the patient relapses, then maintenance therapy with IVIg 0.4 to 1.0 g/kg every 4 weeks is recommended.[130]

Azathioprine is an imidazolyl derivative of mercaptopurine that inhibits DNA synthesis by inhibition of purine metabolism. In PRCA, it may be given at a dose of 2 to 3 mg/kg/day IV and has been found to be effective in patients nonresponsive to cyclophosphamide.[39,131]

Oral cyclophosphamide may be started at a dose of 50 mg PO daily, with a maximal dose of no more than 150 mg daily. Blood counts should be monitored, and the dose may be escalated accordingly. Trials of therapy longer than 3 months without signs of response are not warranted. Monitoring of the reticulocyte count may allow for the early assessment of response. Often, a delayed response may be seen when cyclophosphamide is withdrawn, which reflects the fine balance between adequate immunosuppression and cytotoxicity.*

Rituximab given at 375 mg/m^2 IV infusion weekly for 4 weeks has been found to be efficacious in PRCA. PRCA in a variety of settings, including B-cell CLL, EBV-associated posttransplant lymphoproliferative disease (EBV-PTLD), ABO-incompatible allogeneic HSCT for acute myeloid leukemia, and hairy cell leukemia variant, has been successfully treated.[89,134-137] Owing to the fact that rituximab is specific for B cells alone, cases of nonresponders to it have been reported and attributed to an alternative T cell–mediated pathogenesis.[138] In cases of refractory to immunosuppressive agents affecting T-cell function, rituximab or low-dose alemtuzumab constitutes a reasonable option. Rituximab is effective in patients with PRCA owing to ABO incompatibility following bone marrow transplantation.[89,90]

CsA can be administered at a dose of 5 to 10 mg/kg PO daily in divided doses. CsA can be combined with prednisone at doses of 20 to 30 mg PO. The trough levels of CsA should be monitored, and the dose adjusted to achieve a level between 200 and 300 μg/mL. An adequate trial of therapy is considered 3 months of therapy. The response rates may be as high as 60% to 80%. After a response is achieved, the therapy should be continued for 6 months followed by a slow taper.[103,104,139-145]

Horse ATG may be given to refractory cases at a dose of 40 mg/kg IV daily for 4 days with prednisone at 1 mg/kg. Rabbit ATG (Thymoglobulin) may be given a dose of 2.5 to 3.5 mg/kg daily IV for 4 or 5 days with prednisone at 1 mg/kg. Concomitant prednisone should be administered and then tapered over 2 to 3 weeks. A therapeutic response should occur within 3 months posttherapy, although responses at or beyond 6 months may be observed.[8,103,104,117,146-148]

Daclizumab, an anti–IL-2 receptor antibody (Zenapax, anti-CD25 mAb), may constitute a good alternative to ATG because it does not require hospitalization and is well tolerated. In a recent trial, a dose of 1 mg/kg of body weight IV was administered every 2 weeks. The therapy should be given for at least 3 months. It is possible that combination with CsA may increase the response rate, but no data exist as to the observed response rates.[149,150] Unfortunately, this drug was withdrawn from the market in 2009.

Methotrexate, an antimetabolite, at low doses (7.5 to 15 mg/week PO) is useful in treating PRCA, especially in patients with concomitant LGL leukemia. The responses are generally sustained, and therapy is well tolerated. Methotrexate may be given in conjunction with other therapies like CsA.[12,103]

Alemtuzumab (Campath, anti-CD52 mAb) is a recombinant DNA–derived humanized monoclonal antibody directed against the cell surface glycoprotein CD52, which is expressed on the surface of normal and malignant B and T lymphocytes. It can be given IV or subcutaneously every other day with an initial dose of 3 mg, and subsequent doses can be increased until response is obtained. The usual cumulative dose before response is usually between 200 and 400 mg. Alemtuzumab has been tested in a variety of lymphoproliferative disorders, including diffuse large B-cell lymphoma, B-cell CLL, and T-LGL leukemia. Similarly, PRCA occurring in the context of these conditions previously unresponsive to therapy with steroids, CsA, and even cyclophosphamide (Cytoxan) has been shown to be responsive to this agent. Alemtuzumab can be given either intravenously or subcutaneously.[151-153]

Bortezomib (Velcade) is a proteasome inhibitor containing boron that binds to the catalytic site of the 26S proteasome. It is commonly used in the treatment of multiple myeloma and can be given either intravenously or subcutaneously. A patient who developed isohemagglutinin-mediated PRCA after ABO-mismatched allogeneic hematopoietic cell transplant was successfully treated with IV bortezomib given at 1.3 g/m^2 weekly for 4 weeks. Improvement in reticulocyte counts were noted 30 days after therapy accompanied by an increase in Hgb levels. The patient subsequently achieved complete transfusion independence. Anti-A isohemagglutinin titers were undetectable 30 days after the first dose of bortezomib.[154]

Hematopoietic Stem Cell Transplantation

Despite advances in immunosuppressive regimens, subsets of patients with PRCA remain refractory and are very difficult to treat. As with other bone marrow failure disorders with autoimmune pathogenesis like aplastic anemia, HSCT is an important treatment option especially for refractory and relapsed PRCA cases. Matched sibling donor allogeneic HSCT results in restoration of normal hematopoiesis in patients with refractory PRCA.[155-157] In another case, a patient with relapsed PRCA underwent matched sibling donor allogeneic HSCT combined with donor lymphocyte infusions resulting in full donor engraftment and subsequent return of normal hematopoiesis, suggesting a graft-versus-autoimmunity effect as the likely mechanism for response.[158]

PROGNOSIS

The prognosis of secondary PRCA depends upon the underlying disease. Idiopathic PRCA may be very refractory to treatment. Ultimately, remission may be achieved in a significant proportion (approximately 68%) of patients, especially when sequential regimens are used. Spontaneous remissions are observed in 5% to 10% of cases. Relapses are common, especially during the first year postremission but are usually responsive to the same regimen that induced remission.[103,117] Chronic, low-dose immunosuppressive therapy may be needed in certain cases that have relapsed. In one study, median survival was reported to be 14 years.[117] Unlike a megakaryocytic

*References 3, 4, 104, 117, 132, 133.

thrombocytopenic purpura, evolution to aplastic anemia is rare[112,159] in PRCA, and, moreover, very few patients (3% to 5%) evolve into acute leukemia.[103,117]

ACQUIRED WHITE BLOOD CELL PRODUCTION DISORDER

Neutropenia is a common condition. The majority of cases are secondary to a variety of causes, including systemic or hematologic diseases. In this chapter we will describe a primary, isolated form of neutropenia in which other hematopoietic lineages are not affected. In such a setting, neutropenia may be the result of peripheral destruction or perhaps less frequently the result of the absence of myeloid progenitors in the marrow. Neutropenia may be initially noted during workup for fever and infections or may be an incidental finding on a routine CBC. The cutoff value for the diagnosis of neutropenia is an absolute neutrophil count (ANC) of less than 1500 cells/μL. This value is generally accepted as a definition for neutropenia for all ages and ethnic backgrounds except for newborn infants.[160] Clinically the most concerning consequence of neutropenia is the propensity to develop infections. ANC is the best parameter to assess the severity of neutropenia; however, the correlation between ANC and the propensity for infection is variable in different circumstances and determined by marrow neutrophil reserves, duration of neutropenia, and clinical context.[161-164] This is best illustrated in patients with chronic benign neutropenia of childhood and infancy, where patients may have an ANC as low as less than 250 cells/μL and yet they may be devoid of infections or only have mild infections.[165-167] Instead of ANC, it is the bone marrow neutrophil pool reserve that serves as the most suitable determinant of risk for infection, best evaluated through a bone marrow biopsy. In the setting of neutropenia, should the bone marrow examination reveal depleted neutrophil reserves, the ANC level correlates with the risk for infection. In contrast, if bone marrow shows adequate neutrophil reserves, then ANC levels are not predictive of the risk for developing a serious infection.

CLASSIFICATION OF ACQUIRED NEUTROPENIAS

Neutropenia as a primary disease should be distinguished from inherited forms of neutropenia, which commonly present during early childhood (see Chapter 27), and secondary forms of neutropenia associated with systemic disorders. In addition, idiopathic neutropenia is distinct from the constitutional or familial benign neutropenia frequently seen in African Americans,[168,169] Yemenites, and Falasha Jews or black Bedouins.[170] The degree of neutropenia is often mild, and there is no propensity to develop infections. Most cases of neutropenia are secondary to a variety of disorders. Primary autoimmune neutropenia (AIN) and idiopathic neutropenia are less common. We will limit our description to isolated forms of neutropenia (Table 30-4).

Table 30-4 Classification of Neutropenia

Congenital	
Primary	Autoimmune neutropenia
	Pure white cell aplasia
	Idiopathic
	Thymoma
	Hematologic malignancies (e.g., T-LGL leukemia)
	Infections/postinfectious
	Viral Measles,[219] mumps, roseola,[220,221] rubella,[656] RSV, influenza[218] Hepatitis A,[213] B,[213,214] and C[58] CMV,[222-224] EBV,[215-217] HIV[228,229] Parvovirus[225-227]
	Bacterial Tuberculosis[239,240] Brucellosis[236-238] Tularemia[235] Typhoid fever [234]
	Rickettsial Rocky Mountain spotted fever[657] Ehrlichiosis.[246,247]
	Fungal Histoplasmosis[241,242]
	Parasitic Malaria,[243] leishmaniasis[244,433]
	Autoimmune conditions, (e.g., SLE[658,659], RA[660])
	Drugs and chemicals
	Neutropenia associated with immunodeficiency[317,323]
	Severe nutritional deficiencies[251,252]
	Neutropenia due to increased margination
	Iatrogenic (e.g., hemodialysis[324,325])

CMV, Cytomegalovirus; *EBV,* Epstein-Barr virus; *HIV,* human immunodeficiency virus; *RA,* refractory anemia; *RSV,* respiratory syncytial virus; *SLE,* systemic lupus erythematosus; *T-LGL,* T-cell large granular lymphocyte.

Primary Neutropenia

Most neutropenias are secondary to various hematologic conditions and systemic diseases. However, in a small proportion of cases, an inciting cause cannot be identified despite intensive testing. Such idiopathic cases are most likely autoimmune in nature.

Chronic Idiopathic Neutropenia in Adults

Chronic idiopathic neutropenia in adults compared with those in infancy and early childhood has less tendency toward spontaneous remission, although it does generally remain clinically benign. There may be concomitant anemia or thrombocytopenia that may portend a higher incidence of splenomegaly, infectious complications, and antineutrophil antibodies (ANAs) that are complement fixing.[171] The bone marrow biopsy may show evidence of arrest in myeloid maturation and mild hypercellularity. ANAs may be seen in 36% of patients, suggesting an immunologic pathogenesis.[171]

Idiopathic neutropenias may be chronic and benign in nature or may be associated with significant morbidity. In certain instances immune neutropenia may be associated with hemolytic anemia or with immune thrombocytopenia, but these forms likely represent a distinct nosologic entity. Idiopathic neutropenia can occur at any age, including early childhood. Such cases may be difficult to distinguish from hereditary neutropenia syndromes. AIN may be associated with moderate and severe depression of neutrophil counts. Monocytosis is frequently present.[162,163] Some cases present with splenomegaly, which is to be distinguished from cytopenias associated with hypersplenism in Felty syndrome.[172] The frequency of infectious complications does not correlate with the severity of neutropenia, and patients with severe depletion of neutrophils may remain asymptomatic for long periods of time. Rare cases of chronic idiopathic neutropenia evolving to acute myeloid leukemia have been reported and were associated with point mutations in granulocyte colony-stimulating factor receptor (CSF3R).[173,174]

Conceptually AIN may be due to peripheral autoimmune destruction of neutrophils due to lineage-specific inhibition of myeloid

precursors, with its extreme form being pure white cell aplasia (see Fig. 30-3). Consequently, increased peripheral destruction is associated with marrow hypercellularity and an increased number of myeloid precursors or, if myeloid progenitors are the targets, decreased myeloid precursors and a myeloid maturation arrest. Autoimmune processes have been implicated in the pathogenesis of AIN and could be mediated by both peripheral destruction of neutrophils and inhibition of myelopoiesis.[175,176] The antigens involved in these processes include neutrophil antigens NA1, NA2, ND1, ND2, and NB1 (Table 30-5). Both IgG and IgM antibodies have been implicated. Neutrophil-specific antibodies can be detected using many assays, including specific ELISA, opsonization,[177,178] leukoagglutination,[179] and direct antibody binding.[180] There are several proposed effector mechanisms as to how ANAs can result in neutropenia or affect neutrophil integrity. For example, ANAs may act as opsonins and directly enhance neutrophil destruction.[178] Alternatively, ANAs can indirectly activate, complement, and facilitate opsonization.[181] Immune complexes may also bind to the neutrophil Fc portion, leading to increased neutrophil clearance by the reticuloendothelial system,[182] and finally, ANAs may recognize and damage myeloid precursors.[183] The currently available diagnostic assays used to detect ANAs are generally based on immunofluorescence and agglutination assays. The former allows for the detection of IgM and IgG antibodies from a suspected patient that are attached to normal donor neutrophils detected by flow cytometry performed with the patient's serum and antihuman IgG. The results may be reported as strongly positive, weakly positive, or absent. The second technique, called agglutination assay, uses serum that leads to agglutination of normal neutrophils into either small or large clumps. These tests may help suggest an underlying immunologic process but cannot establish the definite cause. If there is a high index of suspicion that ANAs are the causative factor, some authors suggest that a minimum of two methods be used to detect ANAs, namely, granulocyte agglutination test and granulocyte immunofluorescence test.[184]

In addition to antibodies, T-cell responses may be associated with neutropenia. The most extreme example of such responses is T-LGL leukemia associated with neutropenia and polarized proliferation of CTLs (see later). In AIN, CTL responses are polyclonal and are often accompanied by the simultaneous presence of antibodies. It is likely that specialized CTL clones are capable of recognizing and killing myeloid precursors, interrupting granulocyte production. Consequently some cases of AIN may be amenable to therapy with immunosuppressive agents directed against T cells.

Chronic Benign Neutropenia of Infancy and Childhood

Chronic benign neutropenia of infancy and childhood is considered the most common cause of chronic neutropenia in the pediatric age-group. The majority of cases are autoimmune in nature and show clinical overlap with childhood idiopathic thrombocytopenic purpura and autoimmune hemolytic anemia. It is therefore considered a type of AIN.[185-190] An incidence of 1:100,000 has been reported in a childhood population in Scotland.[189] This form of neutropenia typically presents in children less than 3 years of age, with a median age of 8 to 11 months and with a predominance of girls.[185,187,188] The CBC usually shows an ANC of less than 250 cells/μL with normal morphologic characteristics and normal hemoglobin and platelet count. Occasionally monocytosis, eosinophilia, and mild thrombocytopenia may be present. In this condition, neutropenia is due to chronic depletion of mature granulocytes and is accompanied by a compensatory myeloid left shift in the marrow.[165-167] Most frequent clinical signs and symptoms are oral infections, including bothersome ulcers, but these are often associated with additional functional defects of neutrophils and cellulitis of the labia majora. Of importance is the normal neutrophil count at birth and absence of a history of familial forms of neutropenia. The etiology of this condition is unknown, but the pathogenesis involves ANAs, detectable in the majority of patients.[166,185,187] The antibodies are generally directed against similar antigens seen in adult AIN, especially those involving NA, NB, and ND loci. In about 25% of cases, the antibody is against an allele of neutrophil FcγRIII opsonin receptor called NA1.[185,187,188] Immunosuppressive therapy leads frequently to responses supporting the immune pathogenesis of this disease. Although the neutrophil count can be severely depressed, serious infectious complications are uncommon, and therefore treatment to raise the ANC is generally not indicated except if recurrent infections occur. Antibiotics are useful to treat infections, and granulocyte colony-stimulating factor (G-CSF) has been shown to be effective in elevating neutrophil counts.[191]

SECONDARY FORMS OF NEUTROPENIAS

Clinical Associations

Drug-Induced Neutropenia/Agranulocytosis

Drug-induced neutropenia is common.[192] The association was first described by Kracke in 1931 when agranulocytosis was observed in patients taking aminopyrine. The incidence in various studies is 1.0 to 3.4 cases per million per year.[192-197] Drugs may induce granulocytopenia by (1) direct toxicity leading to inhibition of myelopoiesis frequently observed in drugs like valproic acid,[198] carbamazepine,[199] and β-lactam antibiotics[200,201]; (2) immune-mediated (either antibody- or complement-mediated) as seen with penicillin and antithyroid drugs[202-204] or immune complex–mediated (quinidine)[205] destruction of myeloid progenitors and mature neutrophils; and (3) induction of CTL responses.[206] Genetic predisposition due to polymorphisms in various genes coding for cytokine and cytokine receptors as demonstrated for clozapine with tumor necrosis factor (TNF) and HLA polymorphisms as well as possibly variants of genes coding for a variety of metabolizing enzymes also plays a role.[207,208] Of interest are drugs that directly antagonize important vitamin cofactors necessary in normal bone marrow development. Neutropenia observed in patients treated with trimethoprim-sulfamethoxazole is due to the inhibitory effects on granulopoiesis by trimethoprim, owing to its antifolate action, which is reversed by folinic acid.[209] A similar finding can be seen with methotrexate owing to its antifolate action.

Most patients present with either asymptomatic neutropenia discovered on routine examination or symptomatic neutropenia with infectious complications, including fever, angular stomatitis, or pneumonia. The reported mortality rates vary from 1% to 25%. Most patients recover without further complications. It has been estimated that drugs account for 72% of cases of agranulocytosis. The usual time to development of overt neutropenia is around 1 to 2 weeks, and neutropenia resolves upon discontinuation of the offending drug within 10 to 14 days,[210] although time to recovery may vary depending on whether bone marrow hypoplasia is present (10 days) or not (14 days).[211] The recovery in neutrophil counts is usually preceded by increases in peripheral blood monocytes and immature

granulocytes.[212] The International Agranulocytosis and Aplastic Anemia Study (IAAAS) has identified the most commonly associated agents and the relative odds ratios for developing agranulocytosis (Table 30-6).[197] In some instances, the severity of neutropenia is related to the dose and duration of the therapy. The therapy includes discontinuation of the potentially offending agents. In some instances associated with infections or prolonged recovery, G-CSF may be administered.

Neutropenia as a Manifestation of Systemic Diseases

Postinfectious Neutropenia

Neutropenia is commonly associated with viral infections, particularly in children. Various mechanisms have been implicated in neutropenia associated with systemic viral infections, including inhibition of hematopoiesis, granulocyte sequestration, margination, and peripheral destruction. Neutropenia generally improves when the viremia resolves. Neutropenia has been associated with hepatitis A,[213] B,[213,214] and C viruses,[58,213] EBV,[215-217] influenza,[218] measles,[219] roseola,[220,221] CMV,[222-224] and parvovirus B19 infections.[225-227] Neutropenia is also frequently encountered in patients with AIDS, with approximately 70% of patients being neutropenic during their illness.[228,229] The mechanisms vary and may include antibody formation against neutrophils,[230-232] direct viral inhibition of hematopoietic progenitor cells, abnormal expression of growth factors and other cytokines, and inhibitory effects exerted by HIV-infected accessory cells.[233] The HIV virus not only suppresses hematopoiesis but also increases the risk for acquiring other infections. Furthermore, therapy with antiretroviral agents may dramatically decrease neutrophil counts (see Table 30-4).

Systemic bacterial, fungal, and parasitic infections can be accompanied by neutropenia, including typhoid fever,[234] tularemia,[235] brucellosis,[236-238] mycobacterial infections,[239,240] histoplasmosis,[241,242] malaria,[243] leishmaniasis,[244,245] and ehrlichiosis.[246,247] The pathogenesis includes margination and sequestration of leukocytes as observed in malaria, in which there is reduction in the circulating polymorphonuclear neutrophil (PMN) pool and enlargement of the marginating PMN pool, primarily in the spleen and lung. Neutropenia can be present during sepsis, especially in newborns or debilitated individuals.[248,249] In such situations, neutropenia may be due to inhibition of hematopoiesis by inflammatory cytokines, exhaustion of marrow reserves, or redistribution.[250]

Table 30-6 Drugs Associated With Agranulocytosis

	Etiologic Fraction	
	Agranulocytosis	*Aplastic Anemia*

Neutropenia in Nutritional Deficiency and Nutritional Excess

Malnutrition, dietary restrictions, malabsorptive states, and concomitant intake of inhibitory drugs are just a few common causes of nutritional deficiencies that may lead to neutropenia. Vitamin B_{12} and folate deficiency, frequently associated with megaloblastic anemia, can also manifest with neutropenia. Lack of these essential vitamin cofactors results in the impairment of normal DNA synthesis, leading to abnormal granulopoiesis. A frequently observed morphologic feature is the presence of hypersegmented neutrophils.

Copper deficiency may also be associated with neutropenia.[251,252] Possible mechanisms may include arrest in maturation of neutrophil development as shown in studies in mice[253] and increased antineutrophil antibody formation.[254] Most cases have been found in malnourished infants, in patients with zinc intoxication[255,256] and malabsorption states,[257,258] and in persons receiving total parenteral nutrition without adequate copper supplementation.[259,260] Copper deficiency is often accompanied by a normocytic anemia, whereas platelet counts are invariably normal.[261] Other clinical and laboratory manifestations associated with copper deficiency include presence of ringed sideroblasts in the bone marrow,[262,263] macrocytic anemia,[264] low ceruloplasmin levels,[262] myeloneuropathy,[265] and skeletal abnormalities.[266]

Zinc intoxication in the absence of concomitant copper deficiency has also been associated with neutropenia generally in conjunction with severe anemia. A dysregulation in calprotectin metabolism has been suggested as a mechanism. Calprotectin, also known as the S100A8/A9 or MRP8/14 complex, is a major calcium-binding protein present in the cytosol of neutrophils, monocytes, and keratinocytes that increases during inflammatory states.[267]

Neutropenia Associated With Metabolic Disorders

Various acquired or inherited metabolic conditions may be associated with neutropenia. For example, neutropenia has been observed in patients with ketoacidosis and hyperglycemia, orotic aciduria, or methylmalonic aciduria.[268-271] Similarly, glycogen storage disease type IB is commonly associated with neutropenia responsive to myeloid growth factors.[272-275]

Acquired Neonatal Neutropenias

Neutropenia has been described in infants of hypertensive mothers. In this syndrome, the ANC can be severely depressed for 1 to 30 days

postpartum.[276-278] This type of neutropenia is associated with an increased risk for early-onset sepsis in neonates,[279] a prolonged duration of neutropenia, and an increased risk for neonatal nosocomial infections.[280] Granulocyte kinetic investigations suggested that the neutropenia is the result of diminished neutrophil production. An inhibitor released by the placenta and present in cord blood serum has been shown to play a role in this syndrome.[276,281]

Moderate to severe neutropenia has also been observed secondary to IgG antibodies transferred from mother to infant. This is a condition called *isoimmune neonatal neutropenia* or *neonatal alloimmune neutropenia.* In most cases, antibodies are directed against antigens on neutrophil FcγRIIIb (anti-NA1, anti-NA2, and anti-SH)[282] and NB1,[283,284] but in rare circumstances maternal neutrophil-specific isoantibodies are also produced when there is deficiency of the FcγRIIIb gene.[285-289] The incidence of this condition can be as high as 2:1000 live births.[290] In both neutropenia occurring in hypertensive mothers and isoimmune neonatal neutropenia, differentiation from congenital forms of neutropenia may be difficult. Treatment with G-CSF is usually effective in neutropenia of infants of hypertensive mothers, but higher doses may be needed because preeclampsia-associated inhibitor of rhG-CSF may be present.[278,291,292] IVIg[293] and G-CSF[282,294] are both effective for treatment of isoimmune neonatal neutropenia.

Neutropenia and Hypersplenism

Hypersplenism may be associated with neutropenia, but in most instances other cytopenias will also be present. However, hypersplenism may be a sign of diseases that can result in neutropenia, such as in T-LGL leukemia[106,107,295] and Felty syndrome.[296,297] Other than direct sequestration, another potential mechanism leading to neutropenia may be increased neutrophil apoptosis that normalizes after splenectomy.[298] Recently a high incidence of *Helicobacter pylori* infection has been noted among individuals with neutropenia and splenomegaly. A potential role for the bacterium in the pathogenesis of the splenomegaly is being explored. Conversely one can hypothesize that the bacterium may be the culprit in the development of the neutropenia.[299] Splenectomy either laparoscopically[300] or through laparotomy[301] may be effective in most cases, although in situations precluding splenectomy, intraoperative splenic artery embolization is also effective.[302,303]

Pure White Cell Aplasia

Pure white cell aplasia (PWCA) is a rare condition with pathophysiologic overlap with some forms of AIN associated with myeloid suppression. Similar to PRCA, the pathogenesis may vary and includes antibody-mediated suppression of granulopoiesis,[202,304] T cell–mediated suppression of granulopoiesis, direct myelotoxicity as seen with certain drugs,[305] opsonization of neutrophil precursors in the bone marrow leading to its destruction by macrophages within the bone marrow,[305] and formation of an antibody-drug complex that may damage myeloid progenitors.[306] A bone marrow examination reveals either a total absence of myeloid precursors or arrest at the promyelocyte stage, with megakaryocytes and the erythroid series remaining quantitatively and qualitatively normal. In many cases, a thymoma is present.[307,308] PWCA, if associated with thymoma, has a variable clinical outcome. The complete absence of granulocytic precursors portends a poor response to both immunosuppression and thymectomy and is often fatal, whereas the presence of a maturation arrest at the promyelocyte stage may respond to immunosuppressive therapy.[304,308-311] PWCA has been described in connection with imipenem-cilastatin,[312] ibuprofen,[313] and chlorpropramide.[183] The discontinuation of the offending drug leads to rapid improvement. Recently PWCA has also been associated with primary biliary cirrhosis.[314]

Therapeutic options may include azathioprine,[304] G-CSF combined with plasmapheresis especially if the disease process is antibody mediated,[315] methylprednisolone,[312] IV cyclophosphamide combined with plasmapheresis and G-CSF,[316] and thymectomy.[307] Severe depression of counts may require ATG therapy (see later).

Neutropenia Associated With Immunologic Abnormalities

Acquired and inherited defects of the cellular and humoral immune system may be accompanied by secondary neutropenias. In the inherited immunodeficiency syndromes, the initial presentation is in children and may be associated with failure to thrive. X-linked agammaglobulinemia is a primary immunodeficiency disorder caused by mutations in the gene for Bruton tyrosine kinase (Btk) expressed in both myeloid and B cells that result in the absence of development of B lymphocytes and hypogammaglobulinemia. Neutropenia is seen in 15% to 26% of patients with X-linked agammaglobulinemia, and most suffer from upper respiratory tract infection.[317-319] The exact pathogenetic mechanism is not clear but is believed to be related to the crucial role of Btk in myeloid survival under stress.

Neutropenia is seen in 40% to 50% of patients with X-linked hyper-IgM syndrome[320] and has been associated with defects of myelopoiesis. The most common form of hyper IgM syndrome is due to mutations in the CD40 gene. This defect also leads to a decrease in IgG and IgA. In addition to chronic anemia, children suffer from various infectious complications. They typically lack ANAs and show an arrest at the promyelocyte-myelocyte stage of neutrophil development.[321] Allogeneic HSCT has been curative in some instances.[322]

Common variable immunodeficiency is also frequently associated with neutropenias that can be either chronic or episodic.[323] In addition, hypergammaglobulinemia and hypogammaglobulinemia and T- and NK-cell abnormalities of various causes (both inherited and acquired) can also be associated with neutropenia.

Other Iatrogenic Forms of Neutropenia

Hemodialysis, which is critical in the care of end-stage renal disease patients, can result in neutropenia.[324,325] One important mechanism postulated is through activation of the plasma complement pathway by dialyzer cellophane membranes and generation of C5a (desarg) that causes reversible neutrophil aggregation, resulting in transient neutropenia.[324,326] Similar mechanisms to explain neutropenia have been noted in other clinical settings, including leukapheresis[327] and cardiopulmonary bypass surgery.[328]

LABORATORY EVALUATION

Laboratory studies aim at the identification of the primary causes of neutropenia, as outlined in Fig. 30-4. Idiopathic and autoimmune neutropenia remain, in most instances, diagnoses of exclusion. A careful history, including family history and initial age of first abnormal counts, help to distinguish familial neutropenias (see Chapter 27). Should primary causes such as drugs or systemic diseases be identified, the diagnostic evaluation will concentrate on disease-specific tests. In addition to a CBC and differential, which will help establish the severity of neutropenia, and tests to diagnose a specific disorder such as T-LGL leukemia, a bone marrow examination may be required. Lack of morphologic or cytogenetic signs of primary hematologic diseases (e.g., MDS or aplastic anemia) and peripheral destruction will be supported by the observation of left shift and myeloid predominance. Inhibition of myeloid production is exemplified by an increased erythroid:myeloid ratio.

In some instances, auxiliary tests may help identify the cause of the neutropenia, including vitamin B_{12}, zinc, folate, or copper levels. Determination of immunoglobulin levels may be helpful to establishing the presence of immunodeficiency. Detection of ANAs has a limited significance because most of the currently available routine

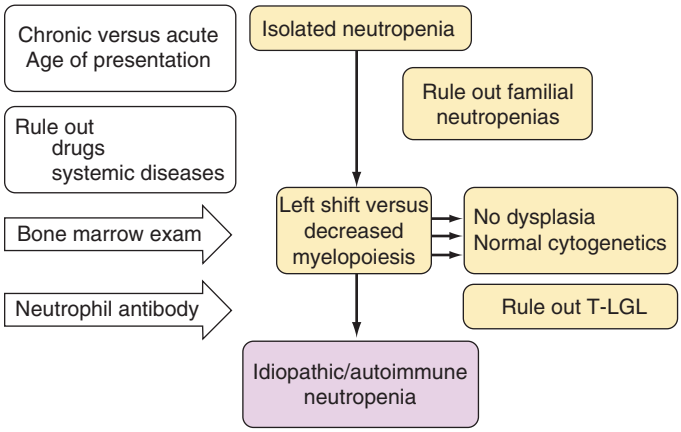

Figure 30-4 EVALUATION OF PRIMARY AND SECONDARY NEUTROPENIA. *T-LGL,* T-cell large granular lymphocyte.

tests are not very sensitive and may not be specific. The presence of antibodies, however, may be helpful and supports the diagnosis of autoimmune forms of neutropenia.

DIFFERENTIAL DIAGNOSIS

Differential diagnostic consideration aims to distinguish primary from secondary forms of neutropenia and to exclude familial hematologic diseases. Suspicion of neutropenia secondary to a primary hematologic disorder requires a bone marrow examination that may be consistent with an early form of aplastic anemia or MDS.

THERAPY

In secondary neutropenias, the therapy is aimed at the primary disease. If potentially offending drugs are present, they should be discontinued. G-CSF (0.5 to 3 μg/kg subcutaneously per day until ANC is above 500 cells/μL) may be used for severe cases of both primary and secondary neutropenias.[275,329,330] It may help to speed up recovery, but if the primary cause persists, it will have only a temporary effect. The use of antibiotics may be useful for the treatment of certain infections. Primary or idiopathic neutropenias most often have an autoimmune cause. Prednisone (1 mg/kg PO daily for 3 months) may be used as first-line therapy,[314] but other B cell–targeted agents may be needed, including rituximab (375 mg/m^2 IV every week for 4 weeks).[331,332] IVIg (2 g/kg IV for 5 days) is effective in certain cases of PWCA.[333] Cytotoxic therapies like cyclophosphamide (Cytoxan) (50 to 100 mg PO daily for 3 to 6 months) may be difficult to administer owing to their inherent myelotoxicity. In cases of neutropenia secondary to lupus or rheumatoid arthritis, such agents may be effective, but the distinction between neutropenia due to the myelosuppressive effects of previous or concurrent treatments for increased activity of the autoimmune disease is necessary. Finally, similar to the treatments applied for T-LGL leukemia, T cell–targeted approaches, such as CsA, can be used (1 to 1.5 mg/kg PO twice a day and titrated to maintain a trough level of 250 to 400 ng/mL).[334,335] A trial of at least 6 weeks is recommended. Similarly use of ATG has also been effective for cases of PWCA[336] and other idiopathic forms of neutropenia.[337] Methotrexate is effective in treating neutropenia related to Felty syndrome[338] and T-LGL leukemia (5 to 7.5 mg/week for 1 to 2 months).[176,339] Of note is that in many instances isolated neutropenias may be asymptomatic, and therapy may not be needed. Alemtuzumab has been used with success in treating thymoma-associated PWCA and other cases of neutropenias.[340-342]

LARGE GRANULAR LYMPHOCYTE LEUKEMIA

Large granular lymphocyte leukemia is a chronic clonal lymphoproliferation of cytotoxic T cells (T-LGL) or NK cells (NK-LGL), often associated with cytopenias, including neutropenia, red cell aplasia, and thrombocytopenia. Pancytopenia is less frequently encountered and may be related to splenomegaly. T-LGL leukemia may be an indolent disorder and present with leukopenia or with lymphocytosis. LGLs observed on a peripheral smear are characteristic of T-LGL leukemia, but their frequency can vary.

T-LGL leukemia results from a proliferation of CTLs and often resembles reactive CTL expansion. It is associated with rheumatoid arthritis (11% to 36%) and B-cell malignancies (5% to 7%)[343] and to a lesser extent with other autoimmune diseases such as Sjögren syndrome,[344] celiac disease,[345] hematologic cancers like MDS, HSCT, and pulmonary hypertension. Most reactive processes are polyclonal, but immunodominant CTL clones may be present, making a distinction between true T-LGL and reactive process difficult (Fig. 30-5). A reduction in the variability of the CTL repertoire can occur in older adults, and clonal or oligoclonal CTL expansions may be more frequent in older individuals. If asymptomatic, this disorder has been termed *monoclonal clonopathy of unclear significance.*

PATHOGENESIS

Inciting Events

T-LGL leukemia frequently arises in the context of a reactive polyclonal CTL expansion undergoing transformation in a manner similar to that proposed for CLL.[346] It is possible also that in T-LGL leukemia one of the effector CTL clones may be initially driven by an exciting antigen, may transform, and consequently the cells fail to undergo apoptosis. The initial or initiating polyclonal response may be a component of the pathophysiologic process associated with infectious agents, rheumatoid arthritis, or other autoimmune disorders.

An initial T cell–mediated process may be responsible for cytopenias in the absence of clonal predominance. In concurrence with this hypothesis, the clinical spectrum of T-LGL is determined by the specificity of the TCR: for example, if myeloid precursors are targets of clonal CTL, neutropenia will be a clinical manifestation. Conversely, if erythroid progenitors are affected, patients will present with anemia (Figs. 30-1 and 30-6). However, unlike the cytopenias that

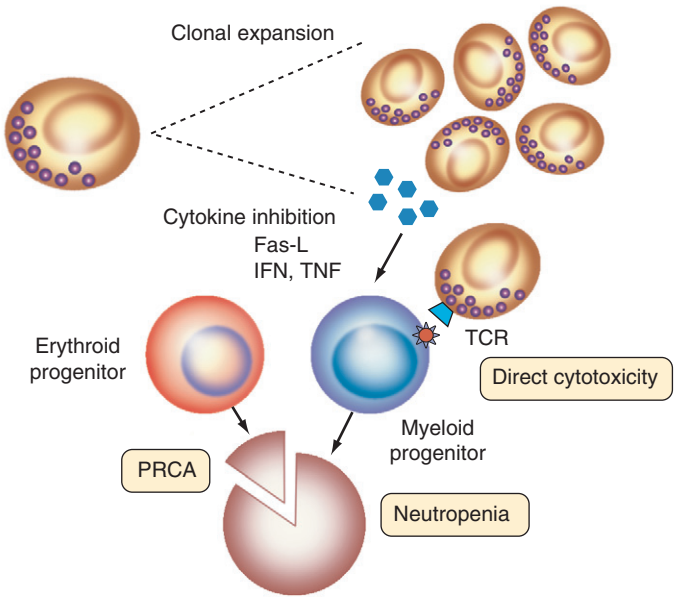

Figure 30-6 PATHOPHYSIOLOGY OF CYTOPENIAS IN T-CELL LARGE GRANULAR LYMPHOCYTE LEUKEMIA. *FasL,* Fas ligand; *IFN,* interferon; *PRCA,* pure red cell aplasia; *TCR,* T-cell receptor; *TNF*, tumor necrosis factor.

resolve following immunosuppression, the CTL clone may persist at a certain level, suggesting that other disease mechanisms involving soluble factors play a role in the development of the cytopenias. Various soluble agents, including Fas ligand (FasL) and perforin, have been implicated in the pathophysiology of the cytopenias in T-LGL leukemia.[347-349]

Clonal Transformation

Clinically T-LGL leukemia does not behave as a typical leukemia: excessive accumulation of malignant cells is often absent, and progression to a more malignant phenotype is rare.[106,350] Instead, the expanded clone in T-LGL leukemia resembles a normal antigen-activated $CD8^+CD57^+$ effector cell; both normal and malignant LGL constitutively express perforin and FasL and can suppress neutrophil development in vitro.[348,351-353] Gene expression studies have shown that the T-LGL leukemia clone exhibits upregulation of cytotoxic proteases and adhesion molecules and downregulation of protease inhibitors.[351,352] Typical clonal LGL cells seem to be terminally differentiated and cannot be effectively expanded in vitro by polyclonal mitogens (unpublished observations).

It is likely that a polyclonal CTL response predates the outgrowth of the immunodominant T-LGL leukemia clone (see Fig. 30-3). The putative transforming event most likely involves a memory cell that feeds into the mature effector CTL compartment.[354] Under normal physiologic circumstances, activated effector T cells are deleted after antigen-driven expansion by Fas-mediated apoptosis. The failure of an activated memory and/or effector clone to undergo apoptosis may result in its persistent expansion.[355-358] LGL leukemia cells express high levels of Fas/FasL, yet themselves are resistant to Fas-mediated apoptosis.[359] It is conceivable that persistent LGL leukemia cell expansion may result from this resistance to homeostatic apoptosis. In addition to the high surface expression of Fas/FasL, soluble FasL has been detected in sera from T-LGL leukemia patients and may contribute to the induction of apoptosis of neutrophil precursors in the bone marrow.[339]

An LGL clone persists mostly in the G_0/G_1 phase of cell cycle,[353] and clonal transformation may also be due to a constitutive overexpression of prosurvival and antiapoptotic transcription factors. STAT3 has been shown to be involved in cellular transformation along with an active Src family kinase[360] and appears to be constitutively activated in T-LGL leukemia cells.[361,362] In addition, a constitutive activation of an Src family kinase in T-LGL leukemia (likely Lck or Fyn) has been reported that may be related to this increased STAT phosphorylation.[363] It has been proposed that STAT3 activation in T-LGL may inhibit apoptosis downstream of Fas receptor signaling by induction of MCL1, a member of the BCL2 family of antiapoptotic proteins.[361] This finding is further supported by data showing that blockade of STAT signaling in T-LGL cells leads to the reversal of Fas resistance. Similarly, constitutive activation of the extracellular signal-related kinase (ERK) mitogen-activated protein kinase pathway seems to play a role in survival of NK-LGL leukemia cells.[364] ERK was found to be constitutively activated in T-LGL as well.[363]

Extreme Clonal Expansion and the Nonrandom Nature of the T-Cell Large Granular Lymphocyte Leukemia Clone

Molecular analysis of the TCR repertoire in T-LGL leukemia has revealed a spectrum of expansion of the T-cell clone in individual patients. In some cases, up to 98% of the peripheral $CD8^+$ repertoire consists of only one clone, a surprising finding given the absence of immunodeficiency among T-LGL leukemia patients. In healthy controls, even the most predominant clones, most likely reactive to ubiquitous antigens, constitute only up to 1.4% of the entire TCR repertoire.[365] Thus detection of an extreme degree of clonal expansion is an important pathologic sign. Similarly, because of the vast diversity of the physiologic TCR repertoire, the probability of isolation of identical CDR3 clonotypes in different individuals is extremely low. We have encountered only a few shared clonotypes even when identical twins were compared. Therefore occurrence of identical and highly similar clonotypes between individual LGL leukemia patients or strikingly homologous clonotypes within the TCR repertoire of an individual patient may lead to the recognition of identical target antigens.[365] This notion might be further supported if patients with identical or highly similar clonotypes share some HLA features, leading to the display of identical antigenic peptides. It is possible that structurally similar clonotypes present in some patients with T-LGL arise in the context of initial polyclonal CTL response and the initial transformation step is not random (see Fig. 30-3). Once a pathogenic immunodominant clonotype is identified and characterized, its sequence can be used for the design of clonotypic TaqMan PCR. This quantitative method may be employed to track the immunodominant clone throughout the course of therapy and thus may potentially predict an impending relapse.[365] Moreover, recent data show that in many cases of T-LGL leukemia the immunodominant clone may change with time as demonstrated by Vβ flow cytometry, suggesting the diversity of the autoimmune process within this disease, and challenges what we know about the leukemic nature of this disease.[366]

Putative Viral Culprits

Although no particular virus has been singled out, according to evidence to date, HTLV-1 (or a related retrovirus) and/or a member of the gammaherpesvirus family are interesting candidates implicated in the pathogenesis of LGL leukemia.[367-371] For instance, patients with NK-cell LGL leukemia are often seropositive for the p21e envelope protein of HTLV-1, known to activate the ERK pathway. HTLV epitope mapping has demonstrated a strong reactivity against env p21e protein, with particular specificity for the BA21 epitope. However, patients seroreactive for this epitope were negative for HTLV-1. HTLV types 3 and 4 were also tested in patients with T-LGL leukemia but results were found to be negative.[372] Consequently it has been hypothesized that a cellular or retroviral protein with homology to BA21 may play a major role in LGL etiology.[367] In

addition, rabbit and bovine LGLs infected with alcelaphine herpesvirus 1 or bovine herpesvirus 2, respectively, have been shown to display several properties of human T-LGL leukemia, such as poor proliferation after mitogen stimulation, constitutive ERK activation, and constitutive Lck and Fyn kinase activity.[373]

New Insights Into the Pathogenesis of Large Granular Lymphocyte Leukemia and Potential Therapeutic Targets

IL-15, a cytokine important in survival and proliferation of T and NK cells, is expressed in LGL leukemia. It signals to a heterodimeric receptor that includes IL-15Rα. The exact mechanism by which this cytokine contributes to leukemic transformation in LGLs has recently been tied to its effect on a small subset of NKT cells which expresses NKp46 in both mice and humans.[374] Experimental data also show that IL-15Rα is increased in the serum of patients with T-LGL leukemia and there is upregulation of expression of IL-15Rα in the peripheral blood mononuclear cells in T-LGL leukemia patients. It was proposed that the higher levels of IL-15Rα may lower the IL-15 response threshold and thus contribute to disease pathogenesis.[375] Although T-LGL and NK-LGL leukemias are typically indolent, certain aggressive forms with rapidly progressive and fatal outcomes exemplified by aggressive NK-LGL leukemia are also encountered. This disease entity does not respond to conventional LGL leukemia therapies. A molecule called survivin, which inhibits apoptosis, is highly expressed in the mitochondria of leukemic NK cells in aggressive and indolent forms of NK-LGL leukemia. Efficient knockdown (80%) of survivin has resulted in death of NK-LGL leukemia cells. The upstream activator of survivin is ERK, and a pharmacologic inhibitor of phosphorylated ERK called nanoliposomal C6-ceramide has resulted in dose-dependent inhibition of survivin expression, offering a potential future treatment option.[376] Polymorphisms of the MHC class-I polypeptide-related sequence A (MICA) noted by single-nucleotide polymorphism array analysis may also be important in the pathogenesis of T-LGL leukemia. MICA is the ligand for the receptor NKG2D. MICA*00801/A5.1 polymorphism is found in higher frequency in LGL leukemia patients. Flow cytometric techniques showed that MICA is much more highly expressed in neutrophils of LGL leukemia patients compared to matched controls. Further experiments showed that Ba/F3 lymphocytes transfected with human MICA*019, and neutrophils from patients heterozygous for MICA*008/Af.1 were efficiently killed by large granular lymphocytes.[377]

CLINICAL PRESENTATION AND PHYSICAL FEATURES

Patients with T-LGL leukemia present at a median age of about 55 years, with an equal male/female distribution. The clinical course may be indolent and chronic. Patients are asymptomatic in one-third of cases. The most common clinical presentation is neutropenia (observed in approximately 85% of patients) often accompanied by infections or neutropenic fever.[106,107,295,350,378-380] However, in contrast to neutropenia associated with other hematologic disorders, LGL leukemia patients may remain surprisingly free of infectious complications for extended periods of time regardless of the depressed ANC. Despite the extreme clonality within the T-cell population (suggesting a decreased antigen recognition spectrum), opportunistic infections are rare. Other single-lineage cytopenias, including PRCA and immune-mediated thrombocytopenia, accompany T-LGL leukemia less frequently than neutropenia.[12,378,379,381,382] In some patients, neutropenia, anemia, or pancytopenia may occur at different times throughout the course of the disease.[383] Pancytopenia may be related to splenomegaly reported in 20% to 50% of patients. Hepatomegaly is present in a minority of patients (10% to 20%). Lymphadenopathy and B symptoms may also occur; however, this is uncommon.[350] It has been reported that pregnancy can improve neutropenia in women with LGL leukemia.[384] Clinical transformation to a more malignant form is rare. The clinical presentation of NK-cell LGL lymphocytosis is very similar to that seen in T-LGL leukemia with regard to lymphocyte counts, associated conditions, treatment responses, and survival, although in some reports there is a lower incidence of neutropenia and anemia.[385]

Clinical Overlap and Associations

In some clinical circumstances, natural or pathologic immune responses can resemble T-LGL expansions. For example, responses to viruses such as CMV or EBV, although of an oligoclonal or polyclonal nature, may display a strong clonal dominance mimicking at times a true clonal process.[386] Consequently, polarized CTL responses in the context of infections have to be distinguished from true LGL leukemia.

T-LGL leukemia can occur concomitantly with several autoimmune diseases. Rheumatoid arthritis is likely the most common association, occurring in one-third of patients with T-LGL leukemia, but other diseases such as ulcerative colitis, Sjögren syndrome, systemic lupus erythematosus, multiple sclerosis, and a number of other (auto) immune conditions have been described.[387-394] Felty syndrome is characterized by neutropenia with rheumatoid arthritis and splenomegaly; 80% of cases express the HLA-DR4 allele, a finding also observed in T-LGL leukemia.[395] This common immunogenetic link and similar patterns of cytotoxic clonal expansion with T-cell infiltration suggest that Felty syndrome and T-LGL leukemia represent components of the same disease process.[387,396-398] In addition, PRCA and immune-mediated thrombocytopenia may also be associated with LGL lymphoproliferation. Clonal expansions that characterize T-LGL leukemia can appear similar to oligoclonal CTL responses elicited by strong immunodominant antigens, including certain viruses[398-401]—thus the distinction between T-LGL leukemia and a reactive lymphoproliferative process. LGL leukemia has also been described after bone marrow and solid organ transplantation, perhaps initiated by an alloantigen or an infectious agent such as EBV.[402-407]

LGL-like cell expansions may also be present in other hematologic disorders, including MDS, aplastic anemia, and paroxysmal nocturnal hemoglobinuria,[380,408-412] and may coincide with a number of lymphoproliferative disorders as well.[388,413-415] In MDS the prognosis is usually determined by the presence of MDS, but the presence of LGL may provide a rational target for immunosuppressive therapy. In MDS, T-LGL leukemia has been reported to negatively affect the outcome of therapy directed against the CTL clone.[411] LGL leukemia has also been described in conjunction with hemolytic anemia following bone marrow transplantation, perhaps a process initially driven by an alloantigen or infectious agent such as EBV.[31] As with infections, distinction between an LGL leukemia and reactive lymphoproliferation may be blurred. For example, neutropenia may be associated with various degrees of clonality, with an LGL leukemia representing the most extreme form of this process.

LABORATORY DIAGNOSIS

Diagnostic criteria remain a subject of considerable discussion (Table 30-7). Traditionally LGL lymphocytosis (identified by morphologic characteristics and flow cytometry) is a significant diagnostic criterion.[295,388] However, not all clonal cells display the typical morphologic features, and some patients present with leukopenia. Consequently an LGL count of greater than 2000/μL of blood has been abandoned as a strict diagnostic requirement, and lower numbers such as 0.400/μL of blood have been proposed.[106,416] Most investigators consider the presence of an expanded homogeneous $CD3^+$, TCR-$\alpha\beta^+$, $CD8^+$, $CD16^+$, $CD28^-$, $CD57^+$ cell population as diagnostic of T-LGL leukemia and $CD2^+$, $sCD3^-$, $CD3\varepsilon^+$, TCR-$\alpha\beta^-$, $CD4^-$, $CD8^+$, $CD16^+$, $CD56^+$, $CD57^{(variable)}$ for NK-LGL leukemia. In almost all patients the expanded clone is $CD8^+$ (only very rarely $CD4^+$),[106,417-419] and in the majority of cases this population also expresses CD57, but

LGL leukemia cases without this marker have been observed.[419] Clinical correlations based on immunophenotypic characteristics have been defined; $CD8^{+(dim)}$/$CD57^{+}$ LGLs are associated with clonal T-LGL leukemia and neutropenia, CD16 expression with complete or partial loss of CD5 is associated with T-LGL leukemia but not cytopenias, and $CD8^{+(dim)}$/$CD57^{+}$ with loss of CD5 expression is associated with T-LGL leukemia with severe neutropenia.[420] In addition, clinically aggressive T-LGL leukemia is characterized by expression of CD26.[421] In most cases of LGL leukemia, CD94 is expressed at increased levels, and other receptors for class I MHC molecules are abnormally expressed.[422-424] Some investigators have suggested that a pool of $CD8^{+}$ memory cells exists that lack CD57 expression but feed into the mature CD57 effector compartment.[354,417] The size of the abnormal clone defining T-LGL leukemia remains controversial. It is likely that the size of the leukemic T-cell population influences the detection of the clonal TCR γ-chain (G) rearrangement by PCR or Southern blotting; thus such tests are considered mandatory for diagnosis.[425,426] These methods may detect a clonal population that represents 15% of the cell population, but it is also likely that smaller CTL expansions may be consistent with latent T-LGL detected only if more precise methods are used. T-LGL can express CD4, but both $CD4^{+}$ as well as double-positive $CD4^{+}$/$CD8^{+}$ cases are rare. Cytogenetic analyses are not useful, although cases with chromosomal aberrations have been described.[427,428]

Table 30-7 Immunophenotype and Laboratory Features of T-Cell Large Granular Lymphocyte Leukemia

Laboratory features

LGL, Large granular lymphocyte; *PCR,* polymerase chain reaction; *TCR,* T-cell receptor.

Flow cytometric analysis of Vβ utilization pattern with antibodies directed against most of the Vβ-chain types may be helpful in making the diagnosis. The Vβ family expansion by flow cytometry does not prove clonality, but it may help assess the contribution of the T-LGL clone to the $CD8^{+}$ or $CD4^{+}$ population (Fig. 30-7).

Rare immunophenotypic variants of T-LGL exist that coexpress CD4 and CD8, lack both of these markers, or use γ/δ TCR instead of α/β TCR chains. Vβ flow cytometry has been used to assess the size of the LGL clone and its Vβ use; Vβ use can be identified in 80% of patients. The current Vβ antibody panel does not cover 25% to 35% of the Vβ spectrum. In usual cases, T-LGL does not express CD56 antigen; the presence of this marker has been associated with a more aggressive clinical phenotype.[429] A monotypic expression pattern of KIR can be found with monoclonal antibodies to CD157b, CD158a, and CD158e (corresponding to the most prevalent KIR genes) in about 50% of patients.[430]

Additional supportive tests include a reticulocyte count, which is low in cases presenting with red cell aplasia. The MCV is usually high. Serologic studies or DNA titer to detect evidence of EBV

Approach to the Diagnosis and Treatment of Acquired Pure Red Cell Aplasia, Acquired Neutropenia, and T-Cell Large Granular Lymphocyte Leukemia

Acquired pure red cell aplasia (PRCA) is characterized by reticulocytopenia, but diagnosis is based on the morphologic absence of erythroid precursors in the bone marrow. Congenital forms of PRCA, including Diamond-Blackfan anemia, need to be distinguished when presenting in young children. In adults, primary idiopathic disease has to be differentiated from secondary forms of red cell aplasia associated with hematologic diseases such as B-cell chronic lymphocytic leukemia, myeloma, T-cell large granular lymphocyte (T-LGL) leukemia, and parvovirus B19–associated chronic reticulocytopenia or acute transient aplastic crisis. The diagnosis of parvovirus B19 infection can be made on the basis of the presence of parvovirus B19–specific immunoglobulin M and by deoxyribonucleic acid (DNA) hybridization techniques. Parvovirus B19–specific polymerase chain reaction can help rule out an ongoing infection. This diagnosis is important because therapy with intravenous immunoglobulin (IVIg) (2 g/kg IV for 5 days) can be curative. The therapy of secondary red cell aplasia includes treatment of the underlying condition. It is also important to distinguish red cell aplasia from myelodysplastic syndromes, which can be associated with erythroid hypoplasia but carry a significantly worse prognosis.

In cases with thymoma, thymectomy is the usual initial treatment approach; however, incomplete responders, nonresponders, and patients who relapse are common, necessitating the addition of immunosuppressive therapy. In patients with idiopathic PRCA, therapy includes immunosuppressive agents such as prednisone (1 mg/kg orally PO for 3 months), cyclosporine A (CsA; 5 to 10 mg/kg PO daily in divided doses for 3 months), or oral cyclophosphamide (50 to 150 mg PO daily for 3 months). Second-line therapies include antithymocyte globulin (ATG; if horse ATG, 40 mg/kg IV daily for 4 days with prednisone at 1 mg/kg, and if rabbit ATG, 2.5 to 3.5 mg/kg daily IV for 4 or 5 days with prednisone at 1 mg/kg) or rituximab (375 mg/m^2 IV every week for 4 weeks).

Neutropenia may be associated with severe infections, but the risk associated with neutropenia depends on its clinical context, severity, and duration. The management of neutropenia must account for its clinical presentation and the risk for possible life-threatening complications and includes supportive care, clinical monitoring, and implementation of prophylactic antibiotics and/or hematopoietic growth factors. Neutropenia in childhood may be due to congenital diseases, be associated with viral infections, or be immune mediated. These three causes are usually self-limiting. In adults, most neutropenias are secondary to other conditions, including hematologic or systemic diseases. In general, drug reactions are a very common cause of neutropenia. Idiopathic or autoimmune neutropenia as a primary disease is a diagnosis of exclusion. The pathogenesis involves T-lymphocyte/natural killer–mediated inhibition of myelopoiesis or antineutrophil antibodies. Immunosuppressive therapy may be employed and includes prednisone (1 mg/kg PO daily for 3 months), methotrexate (5 to 7.5 mg/week PO for 1 to 2 months), CsA (1 to 1.5 mg/kg PO twice a day and titrated to maintain a trough level of 250 to 400 ng/mL), IVIg (2 g/kg IV for 5 days), cyclophosphamide (50 to 100 mg PO daily for 3 to 6 months), or rituximab alone (375 mg/m^2 IV every week for 4 weeks) or in conjunction with myeloid growth factors.

T-LGL leukemia is a chronic, often indolent clonal lymphoproliferation of cytotoxic T cells associated with immune-mediated cytopenias. It may be a part of a continuum of reactive cytotoxic T-cell responses ranging from polyclonal, oligoclonal, to monoclonal expansions as seen in T-LGL leukemia. Persistent antigenic drive or dysfunction of the homeostatic termination of clonal T-cell expansion may be involved, and the abnormal cytotoxic T lymphocyte (CTL) in T-LGL is not entirely autonomous. The pathophysiology of cytopenias includes cytokine effects and direct antigen-specific cytotoxicity. Most patients present with neutropenia. PRCA and pancytopenia are less common. Hemolytic anemia and pancytopenia may be the result of splenomegaly present in a significant minority of patients. B symptoms and lymphadenopathy are uncommon, and many patients remain asymptomatic. The diagnosis is established according to the presence of characteristic LGL lymphocytosis, but in some patients the LGL count may not be very high. The immunophenotype is CD3$^+$, CD8$^+$, CD57$^+$, CD16$^+$, CD56$^-$, and CD28$^-$. CD56 antigen–expressing LGL may be characterized by a more aggressive course. Some cases may coexpress CD4 and CD8. The diagnosis includes detection of T-cell receptor rearrangement. In most instances, expansion of the involved Vβ family may be detected using Vβ flow cytometric clonotyping. T-LGL is often associated with autoimmune diseases, including rheumatoid arthritis and Felty syndrome. T-LGL can accompany myelodysplasia and, in rare instances, aplastic anemia or paroxysmal nocturnal hemoglobinuria. Reactive, often viral infection–associated, CTL proliferation may be difficult to document. Asymptomatic cases are monitored, and development of systemic symptoms or symptomatic cytopenias may prompt therapy. Current treatments include immunosuppressive agents such as prednisone, CsA (1 to 1.5 mg/kg PO twice a day then adjusted to maintain a trough level of 250 to 400 ng/mL for 8 to 10 weeks), oral methotrexate (7.5 mg/m^2 week for 21 months), or cyclophosphamide (50 to 100 mg/day for 3 to 6 months). Chronic long-term therapy may be more effective than high-dose combination chemotherapy applied in B-cell lymphomas. Second-line treatments may involve alemtuzumab or ATG. The prognosis is generally good, and transformation to a more aggressive lymphoproliferative disorder is rare.

infection is usually not needed but may be helpful to distinguish reactive immunologic responses. The rheumatoid factor is frequently positive. Antinuclear antibodies and ANAs may also at times be positive (see box on Approach to the Diagnosis and Treatment of Acquired Pure Red Cell Aplasia, Acquired Neutropenia, and T-Cell Large Granular Lymphocyte Leukemia).[431,432]

Unless additional hematologic diseases, such as MDS, are suspected, bone marrow examination may not be required. Bone marrow biopsy and aspirate should be obtained in cases of pancytopenia or involvement of several lineages. Morphologic hallmarks of MDS and cytogenetic analysis may help establish a diagnosis of MDS.

DIFFERENTIAL DIAGNOSIS

Differential diagnostic considerations include reactive processes such as viral infections. Occasionally MDS may be present simultaneously or serve as an alternative diagnosis; T-cell oligoclonality may accompany MDS.

THERAPY

A significant proportion of patients will be asymptomatic, and the diagnosis may be totally coincidental. Should the patient be asymptomatic, therapy may be delayed. Lymphocytosis may be significant, but absolute lymphocyte counts more than 40,000/μL are unusual. Symptomatic splenomegaly may be an indication for splenectomy. Pancytopenia may be a result of splenomegaly, and the procedure aids in the treatment of a hemolytic anemia that can be present in some patients.

Patients may tolerate significant degrees of neutropenia for many years. Indications for treatment include neutropenic complications or transfusion dependence (Fig. 30-8). G-CSF therapy will increase counts in some patients, but a significant proportion of patients will be refractory or would have delayed response.[229,433-435] Of interest is the observation that high-dose therapy with typical lymphoma regimens such as CVP (cyclophosphamide, vincristine, and prednisone) or CHOP (cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], and prednisone) may be ineffective and therefore

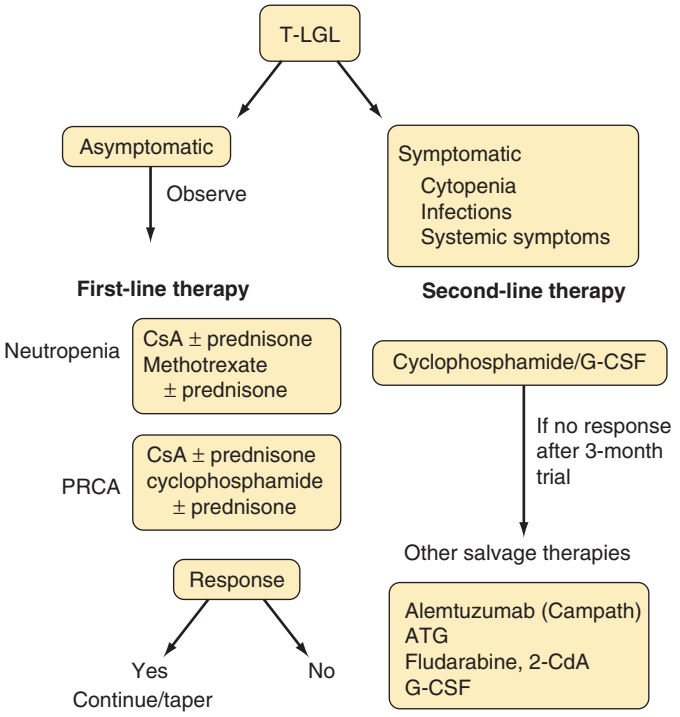

Figure 30-8 THERAPY OF T-CELL LARGE GRANULAR LYMPHOCYTE LEUKEMIA. *ATG,* Antithymocyte globulin; *2-CdA,* 2-chlorodeoxyadenosine; *CsA,* cyclosporine A; *G-CSF,* granulocyte colony-stimulating factor; *PRCA,* pure red cell aplasia; *T-LGL,* T-cell large granular lymphocyte.

should not be used. Cases refractory to bone marrow transplantation have been described.[436] Monotherapy with prednisone may relieve some of the symptoms and improve neutropenia, but remissions are usually not durable. CsA given at 1 to 1.5 mg/kg PO twice a day then adjusted to maintain a trough level of 250 to 400 ng/mL represents a reasonable first-line therapy; however, a course of sufficient duration has to be given, with a response expected after 8 to 10 weeks of therapy.[334,437] Weekly oral methotrexate given at 7.5 to 10 mg/m^2 PO weekly has been used successfully.[437,438] Patients with LGL leukemia–associated PRCA may be better treated with oral cyclophosphamide instead of methotrexate with a dose between 50 and 100 mg/day. In LGL leukemia with associated PRCA, responses may be delayed, and the PRCA may recur after discontinuation of cyclophosphamide therapy, or if insufficient treatment (<6 to 8 weeks) was administered. Therapy with cyclophosphamide in neutropenic patients may be difficult due to myelosuppression. In most refractory cases, ATG has also been used with success.[439] In recent years, successful therapy with alemtuzumab been has reported.[440] CD52 expression determined by flow cytometry is an important predictive factor for response to alemtuzumab.[441] Purine analogues like fludarabine given in combination with mitoxantrone and dexamethasone or with dexamethasone alone have been shown to produce impressive responses of 79%, although these were confined to a small group of patients.[442] Allogeneic HSCT has also been used successfully in some cases.[443,444] Relapses are frequent but usually responsive to the previously effective therapy. Certain patients may require low-dose maintenance therapy with CsA. In some cases, remarkable improvement of cytopenia can be achieved with splenectomy.[445,446]

PROGNOSIS

LGL leukemia is a chronic condition and may be indolent. In general, mortality is low. Transformation to more aggressive forms of lymphomas or leukemias is uncommon. In cases of T-LGL leukemia associated with a primary hematologic disease such as MDS, the prognosis is dependent on the therapy of the underlying problem.

ACQUIRED PLATELET PRODUCTION DISORDER

Megakaryocytes, like all formed elements of the peripheral blood, are ultimately derived from undifferentiated hematopoietic stem cells that exist in a developmental continuum (see Chapter 26).[447] Through a series of still incompletely understood events, stem cells undergo an asynchronous division that gives rise to two daughter cells. One daughter cell remains a stem cell, fulfilling the requirement for self-renewal of the stem cell compartment, and the other commits to developing within a given lineage, likely through the induction of specific transcription factors such as GATA1, FOG-1, and Fli-1, in the case of megakaryocytes,[448,449] and perhaps by downmodulation of other transcription factors, such as c-Myb.[450,451] Lineage-committed progenitor cells are characterized by a loss of "plasticity" and a remarkable capacity for proliferation. The latter is required because approximately 15×10^6 megakaryocytes/kg body weight must be available to produce the roughly 100×10^9 new platelets that are needed daily to maintain a normal platelet count of 150 to 400×10^9/L.[452] As progenitor cell divisional activity proceeds, maturation, as defined by the acquisition of lineage-specific proteins, ensues, largely under the control of the hematopoietic cytokine thrombopoietin.[453-455] After a variable number of mitoses, proliferative activity eventually declines, giving rise to many daughter cells, which are known as *precursors*. Precursor cells are essentially postmitotic and are capable of one or two additional cell divisions at most. They are often morphologically identifiable as belonging to a given lineage and are primarily engaged in the terminal maturation steps that allow them to function as competent members of their lineage. In the case of megakaryocytes, precursor cells undergo nuclear endoreduplication to increase their ploidy (to a mean of approximately 16 N), a characteristic unique to cells of the megakaryocyte lineage.[448,456-462] Nuclear endoreduplication is accompanied by an increase in megakaryocyte cytoplasm and thereby the number of platelets that an individual megakaryocyte can produce.[459]

As discussed in Chapter 26, the process of platelet formation, or thrombopoiesis, occurs during megakaryocyte terminal maturation.[463,464] It is initiated by the development of the demarcation membrane system in the megakaryocyte's cytoplasm.[465] Among the functions of the demarcation membrane system is delineation of platelet fields. These fields are filled with the granules and proteins that ultimately make up the contents of mature platelets. The latter are shed from pseudopods that mature megakaryocytes extend through endothelial cell junctions into the lumen of marrow capillaries. The pseudopods fracture, because of shear stress in the lumen of these capillaries, and release shards of megakaryocytic cytoplasm, or proplatelets, that are the immediate antecedents of circulating platelets. A fully mature megakaryocyte is estimated to produce approximately $1 \text{ to } 1.5 \times 10^3$ platelets. The molecular regulation of this process is beginning to be better understood. It has been shown, for example, that the apoptosis-stimulating gene Bax promotes platelet production.[466] Interestingly, very recent evidence suggests that the life span of circulating platelets is also regulated by the apoptosis proteins. Using the strategy of ethylnitrosourea-inducted mutations, Mason et al[467] have recently demonstrated that mutations in the Bcl-x_L gene lead to synthesis of a form of the protein that no longer inhibits Bax, and that this in turn leads to accelerated platelet death and a heritable form of thrombocytopenia (Fig. 30-9).

Failure in the process of either megakaryocytopoiesis or thrombopoiesis will result in thrombocytopenia. Under either circumstance, platelet production is characterized as "ineffective," either because there is an absolute decrease in available megakaryocyte cytoplasm (failure of megakaryocytopoiesis) or because cytoplasmic development is defective (failure of thrombopoiesis). Selective impairment of megakaryocytopoiesis may also result from damage to the progenitor cell compartment (the burst-forming units–megakaryocyte [BFU-Mk] or colony-forming units–megakaryocyte [CFU-Mk]; see Chapter 26) or rarely from a compromised ability to synthesize thrombopoietin, the chief cytokine regulator of this compartment (Fig. 30-10).[468] Inherent or acquired defects in megakaryocyte precursor cells may lead to ineffective thrombopoiesis.[468,469] The relative

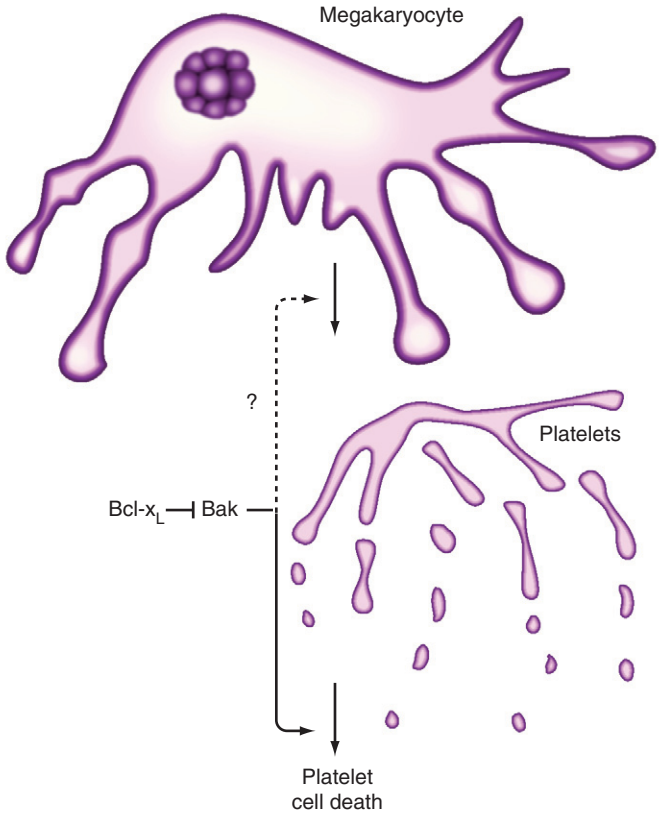

Figure 30-9 Bcl-x_L AND PLATELET LIFE SPAN. Mason et al[467] subjected mice to ethylnitrosourea mutagenesis and screened their first-generation offspring for platelet deficiency. They identified two mutations in the gene encoding the antiapoptotic factor Bcl-x_L that give rise to a dominantly inherited reduction in platelet count. Bcl-x_L appears to promote platelet survival through inhibition of the proapoptotic activity of Bak. Bax promotes production of platelets,[466] and overexpression of antiapoptotic Bcl-x_L impairs the fragmentation of megakayocytes.[592] *(Modified from Qi B, Hardwick JM: A Bcl-x_L timer sets platelet life span.* Cell *128:1035, 2007.)*

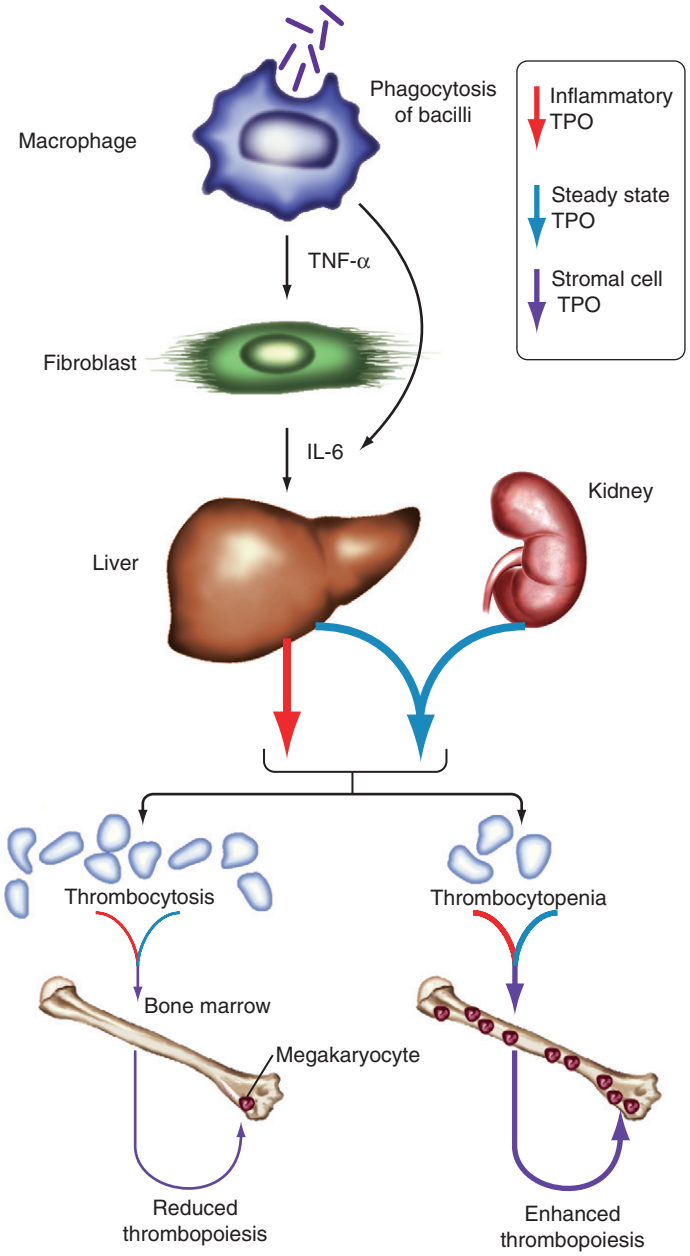

Figure 30-10 THE REGULATION OF THROMBOPOIETIN LEVELS. A steady-state amount of hepatic thrombopoietin (TPO) is regulated by platelet c-Mpl receptor–mediated uptake and destruction of the hormone. Hepatic production of the hormone is depicted. Upon binding to platelet c-Mpl receptors, the hormone is removed from the circulation and destroyed, which reduces blood levels. In the presence of inflammation, interleukin-6 (IL-6) is released from macrophages and, through tumor necrosis factor-α (TNF-α) stimulation, from fibroblasts and circulates to the liver to enhance TPO production. Thrombocytopenia also leads to enhanced marrow stromal cell production of TPO, although the molecular mediator(s) of this effect is not yet completely understood. *(Modified from Kaushansky K: The molecular mechanisms that control thrombopoiesis.* J Clin Invest *115:3339, 2005.)*

effectiveness of platelet production can be calculated by measuring platelet mass turnover, which is defined as the product of the mean megakaryocyte cytoplasmic volume multiplied by the total number of marrow megakaryocytes.[470,470-472] A disparity between cytoplasmic mass and platelet delivery to the peripheral blood (platelet count divided by platelet survival, corrected for splenic pooling) is the hallmark of ineffective platelet production (Fig. 30-11). An examination of the peripheral blood smear is the first step in the initial assessment of patients who present with thrombocytopenia. The presence of platelet clumps, indicative of pseudothrombocytopenia, or abnormally large, or small, platelets can be very useful in generating a differential diagnosis, as can the presence of inclusion bodies in neutrophils. Nevertheless, the current gold standard for diagnosing thrombocytopenia due to ineffective platelet production is a bone marrow aspirate and biopsy. At the moment, direct visualization of the marrow and its cellular contents is the only way to judge the quantity and quality of the megakaryocyte population (Fig. 30-12). However, noninvasive methods for making a diagnosis of ineffective platelet production are being developed. For example, the concentration of serum glycocalicin, the soluble fragment of glycoprotein (GP) Ib, has been shown to be significantly diminished in patients with platelet production abnormalities when compared with normal control subjects.[473] Reticulated platelets, like red blood cell reticulocytes, contain ribonucleic acid (RNA). It has been suggested that as is true for red blood cell reticulocytes, the presence of residual RNA in platelets indicates that they have been newly formed.[473,474] Thus they may be useful for assessing the dynamics of platelet production under baseline conditions and after marrow insults such as chemotherapy or irradiation.[475-478] Platelet RNA can be detected by staining with dyes such as thiazole orange,[474] and it has been suggested that assessing the mean thiazole orange staining can be used to construct a reticulated platelet maturation index.[475] Although appealing in concept, the ultimate usefulness of this assay remains to be determined, because staining artifacts[479] and paradoxically low reticulated platelet counts in cases of disorders characterized by peripheral destruction may complicate the interpretation of such results.[474,479] Yet another approach to assessing platelet production is the measurement

of serum thrombopoietin levels. Thrombopoietin is synthesized constitutively in the liver and then binds to its receptor c-Mpl on megakaryocytes and platelets. Accordingly, in patients with disorders in which megakaryocytes are reduced in the marrow, thrombopoietin levels rise.[474,479-482] However, the wide variation in "normal" thrombopoietin concentrations in serum make this determination somewhat problematic as well. Some of this variability may be attributed to the fact that thrombopoietin synthesis is inducible in marrow stromal cells, perhaps by platelet α-granule proteins.[483,484] Reports attesting to the increased reliability and precision of measuring several of these parameters at once have appeared,[484,485] but it remains unclear whether the expense and time involved will prove cost-effective when compared with the relative simplicity of a bone marrow examination.

As is true for the congenital thrombocytopenias, acquired thrombocytopenia can be caused by a failure of either megakaryocytopoiesis or thrombopoiesis. Of these two possibilities, ineffective thrombopoiesis is the more likely cause, because pure megakaryocyte aplasia or hypoplasia is quite rare. Indeed, thrombocytopenia secondary to decreased marrow megakaryocytes is much more likely to be a prodrome of aplastic anemia, or an early MDS. Clues to these conditions can be found in the marrow, where often subtle abnormalities of other hematopoietic lineages, such as macrocytosis or dyserythropoiesis, can be observed.[486]

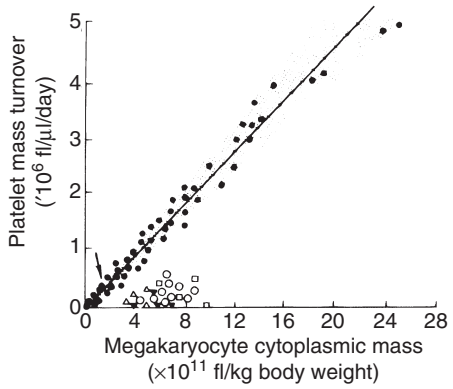

Figure 30-11 INEFFECTIVE PLATELET PRODUCTION. In thrombocytopenia the relationship between marrow megakaryocyte cytoplasmic mass and the turnover of platelet mass in the peripheral blood is usually direct. Platelet mass turnover represents the product of the mean megakaryocyte cytoplasmic volume multiplied by the total number of marrow megakaryocytes. The results in normal subjects are indicated by the *arrow,* and the *stippled area* represents 95% of confidence limits in thrombocytopenic patients with effective production. Ineffective thrombocytopoiesis is identified as a disparity between available marrow substrate (megakaryocyte cytoplasmic mass) and delivery of platelet mass to the peripheral blood (platelet mass turnover). Results in patients with autosomal dominant thrombocytopenia *(open circles),* Wiskott-Aldrich syndrome *(open triangles),* megaloblastic anemia *(open squares),* and preleukemia *(closed triangles)* are characterized by ineffective platelet production. *(Data from Thompson A, Harker L: Quantitative platelet disorders. In* Manual of hemostasis and thrombosis*, Philadelphia, 1983, FA Davis, p 65.)*

SELECTIVE MEGAKARYOCYTE APLASIA

Acquired selective amegakaryocytic thrombocytopenia is quite rare. It is almost always due to an autoimmune mechanism, either antibody or cell mediated. Autoantibodies reacting with megakaryocytes or their progenitor cells, presumably leading to their destruction, have been described.[487] Antibodies directed to cytokines that regulate megakaryocyte development, in particular thrombopoietin, might also play a role in the biogenesis of such disorders. An unusual case of cyclic amegakaryocytic thrombocytopenia due to an antibody to granulocyte-macrophage colony-stimulating factor (GM-CSF) was documented in one patient. Cases of cell-mediated suppression of megakaryocytopoiesis leading to a complete selective megakaryocyte aplasia have also been described.[488] In these cases, suppression was shown in one case to be due to autoreactive T lymphocytes, whereas a macrophage-derived "factor" was implicated in the other. In the

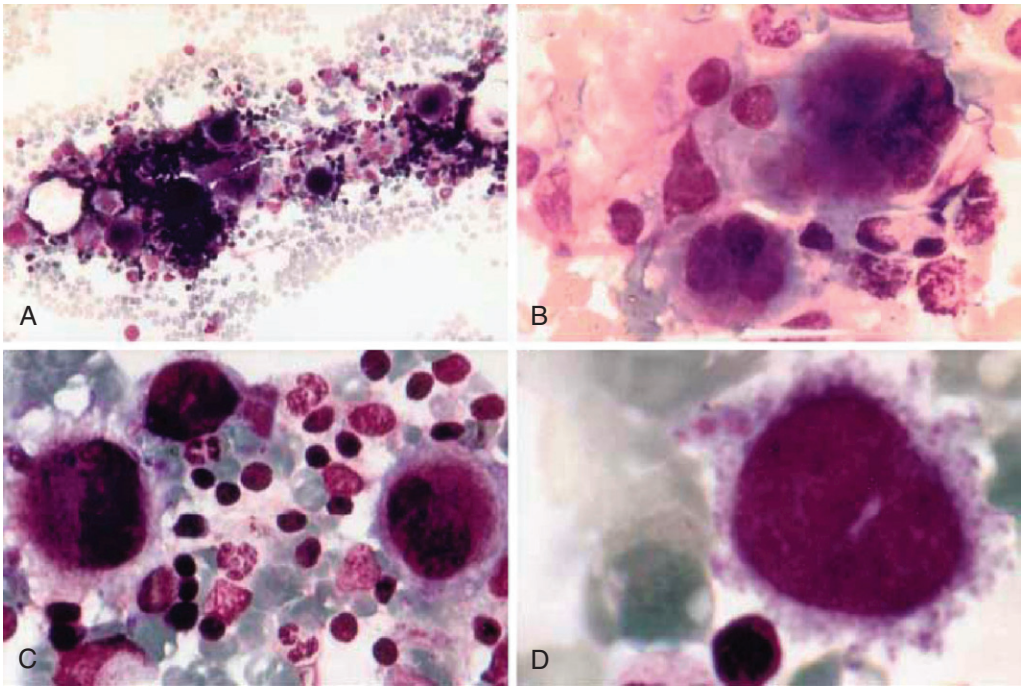

Figure 30-12 MARROW ASPIRATE OBTAINED FROM A CHILD WITH THROMBOCYTOPENIA AND DYSMEGAKARYOCYTOPOIESIS. The megakaryocytes are small and hypolobular, with diminished cytoplasm. Cells are viewed at magnifications of 250× **(A)**, 1000× **(B)**, 200× **(C)**, and 1600× **(D)**. *(From van den Oudenrijn S, Bruin M, Folman CC, et al: Three parameters: Plasma thrombopoietin levels, plasma glycocalicin levels, and megakaryocyte culture, distinguish between different causes of congenital thrombocytopenia.* Br J Haematol *117:390, 2002.)*

latter case, suppression was shown to be specific for megakaryocytes, because no significant effect on BFU-E– or CFU-E–derived colony formation by autologous marrow mononuclear cells was reported.

Patients in whom an autoimmune mechanism is operative may respond to treatment with cyclosporine and ATG, achieving durable remissions.[489] Cytotoxic antibodies directed toward the CFU-Mk may be treated with corticosteroids, plasmapheresis, IV IgG, danazol, cyclosporine, or cyclophosphamide.[490] In a patient in whom an IgG antibody was found to be blocking GM-CSF action, a complete response to cyclophosphamide was observed.[491] Patients with T cell–mediated inhibition of megakaryocytopoiesis may respond to ATG, cyclosporine, or hematopoietic growth factors.[490] If a particular drug or toxin exposure is believed to be responsible, for example. ethanol or a thiazide diuretic, then withdrawal of the offending agent is obviously indicated. If the cause is viral, IV IgG or anti-HIV therapies are indicated.[490] Despite the various causes of ineffective thrombopoiesis, immunosuppressive therapy was found to be effective in 8 of 30 patients in one series.[492] Therefore, although worth trying, most patients do not respond to this form of therapy, and for these individuals, HSCT remains an option. Treatment with intensive immunosuppressive therapy may not prevent progression to aplastic anemia.[491]

INFECTION

Many infectious diseases are associated with thrombocytopenia, and it is likely that infection is the greatest noniatrogenic cause of ineffective platelet production.[493] Infectious agents associated with decreased platelet counts include mycoplasma,[492] mycobacteria,[494] ehrlichiosis,[495] and malaria.[496] In these disorders, the cause of the thrombocytopenia is believed to be diminished platelet production,[497] although immune-mediated thrombocytopenia has also been described in some patients.[494]

Viral infections are by far the most common infectious agents associated with thrombocytopenia due to ineffective megakaryocyte or platelet production. Thrombocytopenia has been reported in cases of mumps, rubella, measles, varicella, CMV, infectious mononucleosis, chickenpox, dengue and other hemorrhagic fevers, hepatitis, and parvovirus infections.[498-501] Live measles virus vaccination can also induce thrombocytopenia due to decreased production.[502] The mechanism responsible for viral suppression of platelet counts is not completely clear. It is known that megakaryocytes are capable of being infected by a variety of viruses. Infected cells may appear dysplastic, with inclusion bodies, vacuoles, or degenerating nuclei. Naked megakaryocyte nuclei may be seen in particular after HIV infection.[497] That such cytopathic cells might have trouble producing platelets is not difficult to imagine.

Perhaps the best studied virally induced thrombocytopenia is that associated with HIV infection.[503] Mild to moderate reduction in platelet counts is quite common in patients with this disease. In a large study (738 patients) of HIV-positive patients with hemophilia, the cumulative frequency of thrombocytopenia 6 years after seroconversion was 16% for children and 18% for adults. At 10 years the frequency increased to 27% in children and 43% in adults.[504] In another study, the frequency of thrombocytopenia was 16% among 103 homosexual men and 37% among 182 IV drug users with a new diagnosis of HIV infection.[505] Thrombocytopenia was also reported to be relatively common in HIV-negative homosexual men (3%) and IV drug users (9%). It was speculated that this might be due to the high rates of hepatitis in these patient groups.[505] Except for patients who acquire HIV in the background of hemophilia, bleeding secondary to thrombocytopenia is unusual, because the counts are rarely less than 50,000/μL. Thrombocytopenia may precede frank immunodeficiency but does correlate with viral load and depletion of the CD4 T-cell population.[490,506]

The principal cause of thrombocytopenia appears to vary with the stage of disease. A retrospective study of 85 patients with HIV and thrombocytopenia suggested that in the early stages of infection, platelet destruction is predominant, whereas in patients with full-blown AIDS, thrombocytopenia is more often due to a production defect.[507,508] Thrombocytopenia due to platelet production abnormalities may be related directly to an HIV infection, to adverse effects of drug therapy, or to secondary malignancy or myelodysplasia. Platelet kinetic studies have shown that patients infected with HIV have a moderate reduction in platelet survival, but all have decreased platelet production regardless of the degree of thrombocytopenia.[507,509] HIV has been shown to infect megakaryocytes directly, as evidenced by finding HIV messenger RNA (mRNA) and p24 antigen in megakaryocyte cytoplasm.[510-512] The portal of entry might be through megakaryocyte surface CD4,[511,512] but more recent studies suggest that CXCR4, which is expressed on megakaryocytes[513] and is a critical coreceptor for viral uptake, is more likely involved.[514] In these studies, infection with HIV-1 env-pseudotyped luciferase reporter viruses indicated that X4 env (CXCR4-using) pseudotypes infected megakaryocytic cells whereas R5 env (CCR5-using) pseudotypes did not.

Examination of a bone marrow aspirate and biopsy specimens may be required to assess whether infiltration by granulomatous infection or a malignancy is contributing to, or causing, the thrombocytopenia in an HIV patient. Assuming no other obvious cause of the thrombocytopenia, and the presence of typical megakaryocytic morphologic abnormalities, antiretroviral therapy is the principal treatment. Zidovudine was the mainstay in the past,[506] but current combination antiretroviral regimens will likely be more effective in increasing platelet counts as well as enhancing CD4 cell counts and reducing HIV viral loads.[502,515,516] For patients with severe and/or symptomatic thrombocytopenia, immune thrombocytopenia purpura (ITP) regimens may well be effective. These include prednisone (1 mg/kg/day) or short courses of dexamethasone.[503] IVIg may be effective in low weekly doses (0.04 g/kg per week),[517] and anti-D has been used extensively in these patients.[503] Splenectomy is quite effective therapy when the therapies described are either ineffective or contraindicated, and it appears to have no adverse effect on HIV progression.[518]

CHEMOTHERAPY AND IRRADIATION

Chemotherapy and irradiation reliably damage bone marrow in a dose-dependent fashion. Megakaryocytes and their progenitors seem to be particularly sensitive to the effects of these agents. As a result, thrombocytopenia is one of the most frequent adverse effects of total body irradiation[519] and chemotherapy. Allogeneic or autologous marrow transplantation is often complicated by prolonged thrombocytopenia, which may persist long after restoration of neutrophil and red blood cell counts. Transplantation of umbilical cord stem cells is also associated with delayed platelet recovery. In one study of 39 pediatric patients receiving such transplants, the median time to platelet count recovery was 49 days (range, 15 to 117 days).[520] The explanation for the tardiness of platelet recovery in these instances is not always clear, but ineffective thrombopoiesis has been shown to be important in at least some cases.[521] Various strategies to ameliorate this problem have been tried, including the use of peripheral blood "stem cells," which may lead to a faster rate of platelet recovery when compared with marrow transplantation. More recently, attempts have been made to expand megakaryocyte progenitor cells, either with a recombinant form of thrombopoietin[522] or other cytokines.[523] The clinical utility of this approach, or the simple administration of recombinant thrombopoietin after transplantation, remains uncertain[524] but might eventually prove useful.[525] Accordingly, posttransplantation thrombocytopenia remains a problem.[526]

Isolated thrombocytopenia with decreased megakaryocytes has been reported after chemotherapy for acute myeloid leukemia. Cyclosporine was reported to augment the platelet count in such patients.[527] Recombinant thrombopoietin has not been shown to be useful in this setting and appears to induce marrow changes suggestive of a myeloproliferative disorder, which is reversed when the thrombopoietin is discontinued.[528]

Alkylating agents in general produce more prolonged thrombocytopenia than antimetabolites. It has been claimed that some

alkylating agents spare megakaryocytes (e.g., cyclophosphamide), but this is a relative phenomenon. Agents such as busulfan, the nitrosoureas, or platinum may cause cumulative damage of the more primitive progenitor cells. Other chemotherapeutic agents, such as the vinca alkaloids, may not decrease the platelet count significantly.

Potential mechanisms for the relative sparing of platelet production by certain chemotherapeutic regimens have been investigated.[529] In one study, for example, potential platelet-sparing mechanisms of chemotherapy regimens containing paclitaxel and carboplatin have been explored by examining (1) normal donor- and chemotherapy patient–derived erythroid (BFU-E), myeloid (colony-forming unit–granulocyte-macrophage [CFU-GM]), and megakaryocyte (CFU-Mk) progenitor cell proliferation in vitro; (2) P-glycoprotein and glutathione *S*-transferase (GST) messenger RNA expression; (3) serum thrombopoietin, stem cell factor, IL-6, IL-11, IL-1b, IL-8, and tumor necrosis factor-α levels in patients treated with paclitaxel and carboplatin; and (4) stromal cell production of thrombopoietin and stem cell factor after paclitaxel and carboplatin exposure. It was found that CFU-Mk was more resistant to paclitaxel alone, or in combination with carboplatin, than CFU-GM and BFU-E. Although all progenitors expressed P-glycoprotein and GST mRNA, verapamil treatment significantly, and selectively, increased the toxicity of paclitaxel and carboplatin to CFU-Mk, suggesting an important role for P-glycoprotein in megakaryocyte drug resistance. Compared with normal controls, serum thrombopoietin levels in patients receiving paclitaxel and carboplatin were significantly elevated 5 hours after infusion and remained elevated at day 7 (287% ± 63% increase; $P < 0.001$). Marrow stroma was shown to be the likely source of this thrombopoietin. It was concluded that P-glycoprotein–mediated efflux of paclitaxel, and perhaps GST-mediated detoxification of carboplatin, results in relative sparing of CFU-Mk, which may then respond to locally high levels of stromal cell–derived thrombopoietin. The confluence of these events was hypothesized to bring about the platelet-sparing phenomenon observed in patients treated with this form of combination chemotherapy.

For patients who suffer from severe or prolonged thrombocytopenia, reducing the intensity of the chemotherapy is the most appropriate approach to management. It had been anticipated that the use of recombinant thrombopoietin might significantly ameliorate this problem, but unfortunately this has not yet been demonstrated.[530] The formation of antibodies to a thrombopoietin derivative, with resulting profound thrombocytopenia, has significantly slowed clinical investigations of this cytokine.[531] Administration of the compound intravenously instead of subcutaneously might avoid at least some of this observed immunogenicity.[530] A number of other cytokines have also been reported to raise platelet counts in this setting, including IL-1, IL-3, IL-6, and IL-11, but most are no longer available and their clinical utility was not clearly demonstrated.[532-537] Only IL-11 is currently approved for the treatment of thrombocytopenia following chemotherapy. Newer thrombopoietin mimetic drugs have recently entered clinical trial. It is thought that they will be less immunogenic, and in disorders such as ITP they appear to have activity.[538] Whether they will be of help in patients with impaired thrombopoiesis is undetermined, but this will no doubt be evaluated in the near future.

At the present time, supportive therapy with platelet transfusions and drugs such as ε-aminocaproic acid for patients who have become refractory to platelet transfusions remain the mainstays of therapy. Amifostine, a phosphorylated aminothiol agent used primarily in the treatment of MDS, has been reported to have cytoprotectant value and to ameliorate the neutropenia and thrombocytopenia in patients being irradiated or receiving various types of chemotherapy in a phase III study.[539]

NUTRITIONAL DEFICIENCIES

Thrombocytopenia of various degrees can be observed in patients with either folate or vitamin B_{12} deficiency.[540-542] In some cases, it can be severe.[543,544] The mechanism of thrombocytopenia is ineffective platelet production.[456] Megakaryocyte numbers are normal or increased in the marrow, and platelet survival is normal or slightly shortened.[545] Vitamin B_{12} deficiency was reported to cause a case of amegakaryocytic thrombocytopenia.[546] Folate deficiency is frequently associated with ethanol abuse, and the etiology of the thrombocytopenia in patients who abuse ethanol is often complex.

Examination of a peripheral blood smear will typically show macrocytosis and hypersegmented neutrophils in addition to thrombocytopenia. The bone marrow often, but not always, shows megaloblastic changes in the erythroid and myeloid lineages.[547] Megakaryocytes are normal in number. Some may appear large, and in some cells multiple disconnected nuclear lobulations have been described. Often, however, distinctive morphologic abnormalities of the megakaryocytes are not seen. Rapid recovery of the platelet count can be achieved with administration of the appropriate vitamin.

IRON DEFICIENCY

Patients with iron deficiency typically exhibit thrombocytosis, but rare patients may become thrombocytopenic.[548] In some instances, decreased megakaryocytes are seen in the marrow,[549] but in a study of six children with severe iron deficiency when bone marrow examinations were performed in three patients, all showed increased numbers of megakaryocytes. After treatment with therapeutic doses of oral iron, each of the patients showed rapid increases in their platelet counts. The increased numbers of megakaryocytes and the extremely rapid increase in platelet counts after initiation of iron therapy suggested an essential role for iron in a late stage of thrombopoiesis.[550] Curiously, thrombocytopenia has been caused by iron therapy in a patient with severe iron deficiency. It was suggested, but not addressed experimentally, that the profound anemia caused preferential development of erythroid cells with a consequent decrease in megakaryocytes because they share a common progenitor.[551]

MARROW INFILTRATION

It is not rare for marrow infiltrative diseases of any type to cause ineffective hematopoiesis. Blood cell production disorders are commonly observed when the marrow is involved with metastatic cancer, lymphoma, or leukemia. Table 30-3 categorizes the infiltrative processes associated with thrombocytopenia. Physical replacement of marrow is the cause of the thrombocytopenia in many cases; it is also possible that inhibitory factors produced by the infiltrating cells are toxic to the cells of the megakaryocytic lineage or interfere with normal regulatory mechanisms. The diagnosis of infiltrative disease is made by marrow examination, although diagnostic clues are usually provided by history, physical examination, and a leukoerythroblastic blood smear. The marrow shows decreased megakaryocytes, which may be larger than normal because of a compensatory physiologic response to the thrombocytopenia. The treatment approach is specific to the infiltrative process.

ETHANOL-RELATED DISORDERS

Ethanol abuse is very commonly associated with thrombocytopenia, which may result from several different mechanisms.[542,552-557] These include, most commonly, increased splenic pooling as a result of portal hypertension and ineffective production related to folate deficiency (which may lead to severe thrombocytopenia). Ethanol itself can be directly toxic to the marrow.[555,558,559] In vitro studies have shown that alcohol concentrations achievable in vivo inhibit megakaryocyte maturation but do not inhibit CFU-Mk.[555,558] Megakaryocyte numbers usually are normal, but markedly decreased megakaryocytes have been observed.[555] In one such case, labeling with platelet-specific antibodies demonstrated that numerous, small, unidentifiable cells were immature megakaryocytes.[555] Rarely, marrow panhypoplasia has been observed in association with alcohol ingestion.[559] Anemia and

macrocytosis accompanied by megaloblastic changes and ringed sideroblasts in the erythroid marrow are typically observed in the marrows of patients who abuse ethanol. The severity of the anemia shows no correlation with the thrombocytopenia. Treatment consists of withdrawal of ethanol and administration of a normal diet. Recovery of the platelet count, often with a rebound thrombocytosis, usually occurs within 2 weeks.

OTHER DRUG-RELATED DISORDERS

A variety of drugs and toxins have been implicated in isolated platelet production defects. Estrogen, for example, has been reported to decrease platelet counts through an unknown mechanism.[560] Thrombocytopenia due to thiazide diuretics has been reported frequently.[561] Although the cause of the thrombocytopenia in most cases is probably increased clearance, decreased marrow megakaryocyte numbers have been noted.[562] Interferons and IL-2 may induce thrombocytopenia.[563,564] The most likely explanation is an inhibition of CFU-Mk. Anagrelide is a very useful drug for lowering platelet counts in patients with myeloproliferative disorders and appears to work by reducing megakaryocyte size and ploidy and by disrupting maturation.[565]

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is a clonal disorder resulting from mutations in the X-linked gene PIGA that encodes for an enzyme required in the initial step of biosynthesis of glycosylphosphatidylinositol anchors (PNH is discussed in Chapter 29).[566] Approximately 25% of patients with PNH have significant marrow aplasia.[567] Thrombocytopenia at diagnosis is a poor prognostic indicator. Because platelet survival is usually normal in cases of PNH,[568] thrombocytopenia is due to decreased or ineffective platelet production. Megakaryocyte progenitors have a decreased proliferative activity and exhibit increased sensitivity to complement.[448,569,570] Treatment with ATG or G-CSF and cyclosporine has ameliorated the thrombocytopenia in some patients,[571,572] whereas marrow transplantation has resulted in long-term remissions in patients with aplasia associated with PNH.[573]

Refractory Thrombocytopenia Due to Myelodysplasia

MDSs may present as isolated thrombocytopenias in a very small number of cases (<1%).[574] The diagnosis of MDS should be considered when there are clonal chromosome abnormalities. Typically they involve chromosomes 3, 5, 8, or 20, but partial deletions of other chromosomes have also been reported.[575] The usual laboratory findings include macrocytosis of platelets and red blood cells. Small dysplastic megakaryocytes, sometimes present in increased numbers, are the most typical abnormalities observed.[574,576,577] Dysplastic erythroblasts or myeloid cells may also be noted.

The clinical course of patients with this type of disorder is progressive. Additional cytopenias invariably develop so that the patient then has a typical MDS. A significant number of cases will evolve into an acute myeloid leukemia.[574] Therapy has not been shown to be beneficial. Some patients with a full-blown MDS associated with marked thrombocytopenia and less than 10% blasts have been reported to experience increases in platelet counts after androgen therapy.[578] As noted earlier, amifostine may be beneficial for some patients. It has been reported that some of these patients have been misdiagnosed as having ITP and treated for this disease. Because such therapy is not useful or helpful, it is important to recognize this entity. Thrombopoietin agonists like romiplostim have also been used in patients with MDS. In an initial study involving 44 patients, a durable platelet response was achieved in 46% of patients with less bleeding events and transfusions seen in patients who achieved a durable response.[579]

Cyclic Thrombocytopenia

Cyclic oscillations in the platelet count have been reported many times in the literature.[491,580-585] The fluctuations in platelet count can be extreme, with thrombocytopenic bleeding being the result.[586] Women are often affected, and in such patients the cycling occurs in association with the menstrual cycle. A study of 10 patients with cyclic thrombocytopenia suggested various causes of the thrombocytopenia, with cyclic variations in platelet production being

Diagnosing Thrombocytopenia Due to Impaired Thrombopoiesis

Compiling a thorough patient history is the first step in a complete workup of a thrombocytopenic patient. Many potential causes will be revealed by a good history, including obtaining a family history of thrombocytopenia, recent infection, medication or substance ingestion, or radiation or chemotherapy.

A careful physical examination could also contribute to making a diagnosis. For example, physical findings suggesting any of the inherited disorders described earlier might be discerned, as might findings suggestive of malignancy such as enlarged lymph nodes. Splenomegaly itself is not indicative of a platelet production abnormality but is often found in patients with lymphoma or other processes associated with marrow infiltration and damage that might cause impaired thrombopoiesis.

The peripheral blood smear is next examined, and this is needed to rule out pseudothrombocytopenia. Moreover, the blood smear provides additional clues to both the pathophysiologic mechanism of the thrombocytopenia and the diagnosis. For example, giant platelets suggest a hereditary or myelodysplastic syndrome; oval macrocytosis and hypersegmented neutrophils suggest a folate or vitamin B_{12} deficiency; and a leukoerythroblastic smear points to an infiltrative process.

Examination of the bone marrow is also required to evaluate megakaryocyte number and morphologic features. A biopsy specimen is more reliable than an aspirate to determine whether megakaryocytes are decreased in number. However, an aspirate showing abundant megakaryocytes in the presence of thrombocytopenia is sufficient to suggest platelet destruction or ineffective production. Megakaryocytes are not evenly distributed throughout the marrow, so examination of many fields is required in order to determine if adequate numbers of cells are present. Megakaryocyte morphologic characteristics are also useful to observe. The normal compensatory response to thrombocytopenia is enlargement of the cells with increased ploidy. Small, microlobulated or hypolobulated megakaryocytes may be seen in myelodysplastic syndromes. Dysmorphic megakaryocytes may be also observed in viral infections, including human immunodeficiency virus. In the future, flow cytometry may provide a more objective analysis of megakaryocytes.

Ultimately a diagnosis of ineffective thrombopoiesis is made by exclusion. The marrow examination reveals quantitatively normal megakaryocytes, and the apparent absence of peripheral platelet destruction together with the appropriate clinical circumstances (e.g., folate or vitamin B_{12} deficiency) often point to this mechanism. Platelet function tests may be helpful in distinguishing ineffective production from platelet destruction. In destructive processes such as immune thrombocytopenia, function is normal, whereas in ineffective platelet production impaired function is not uncommon, as noted earlier. In complex cases, platelet survival studies may be necessary to show that consumption or splenic pooling are not significant contributors to the thrombocytopenia; however, survival studies are rarely required for clinical purposes. In the future, flow cytometric estimation of platelet production rate and measurement of thrombopoietin levels may permit a more facile approach to the differential diagnosis of thrombocytopenia.

responsible for some cases, including the 2 male patients in that group.[587] A case with antibodies toxic to megakaryocytes has also been reported.[482] The possibility that fluctuating cytokine levels may contribute to the pathogenesis of the disorder has been raised by several studies, although it is difficult to distinguish cause from effect.[489,588,589] Cyclic thrombocytopenia may rarely be a presenting manifestation of myelodysplasia.[590] Treatment has been variable; responses to low-dose contraceptives and IV gamma globulin have been reported (see box on Diagnosing Thrombocytopenia Due to Impaired Thrombopoiesis).[582,591]

CHAPTER 31

PATHOBIOLOGY OF THE HUMAN ERYTHROCYTE AND ITS HEMOGLOBINS

Martin H. Steinberg, Edward J. Benz, Jr., Adeboye H. Adewoye, and Benjamin L. Ebert

Anemia, polycythemia, and functional derangements of the human erythrocyte together represent a common group of human disorders with a significant impact on public health. Although sickle cell disease, hemoglobin E (HbE)–associated disorders, and the thalassemias are humankind's most common single-gene diseases, the relevance of red blood cell (RBC) disorders to general medicine extends beyond their individual clinical severities or the number of patients affected. A critical added dimension of erythrocyte disorders is the extraordinarily detailed knowledge available about the basic biochemistry, physiology, and molecular biology of the human RBC and its membrane; enzymes; and major component, hemoglobin. RBCs are especially abundant, relatively simple, and readily accessible for repeated testing in individual patients. These features have facilitated rapid application of the techniques of cellular and molecular biology to studies of the RBC, its component molecules and structures, and syndromes resulting from abnormalities of these entities. Taken as a group, erythrocyte disorders are better understood at the molecular and cellular levels than disorders of any other cell or tissue. It is for this reason that these conditions merit particularly careful scrutiny by students of hematology.

This chapter reviews concepts about normal RBC homeostasis that form the essential knowledge base for understanding anemias, polycythemias, and functional erythrocyte disorders. The primary focus and the object for detailed discussion within this chapter is hemoglobin, the major component, both quantitatively and qualitatively, of the erythrocyte. Hemoglobin molecules dominate the pathophysiology of many RBC disorders and modulate most of the others, in part because of their sheer quantitative predominance in RBC cytoplasm. The other major relevant aspects of human RBCs—the membrane, the enzymes used for intermediary metabolism, differentiation and development, and the process of destruction—are discussed in detail in the introductory portions of other chapters. This chapter surveys these areas only briefly. Detailed descriptions of the RBC membrane can be found in Chapter 43. RBC enzymes and enzymopathies are described in Chapter 42; differentiation and development are described in Chapter 24; regulation of the RBC mass by erythropoietin is discussed in Chapter 24; and the necessary aspects of RBC destruction are considered in Chapters 32, 41-44.

ESSENTIAL FEATURES OF RED BLOOD CELL HOMEOSTASIS

As discussed in Chapter 24, the mature RBC is the product of a complex and orderly set of differentiation and maturation steps beginning with the pluripotent stem cell. By incompletely understood mechanisms involving hierarchic networks of cytokines, a portion of these cells becomes committed to differentiate along the erythroid pathway. Commitment to erythropoiesis provokes a progressively increasing sensitivity to the stimulatory actions of the hormone erythropoietin. As differentiation proceeds, there is preprogramming of certain genes whose expression at high levels will be required during the maturation phase of erythropoiesis. Genes coding for molecules defining the RBC phenotype (e.g., globin) are poised for activation at later maturation steps.

Intermediate progenitor cells arising during differentiation have been characterized experimentally, including the burst-forming unit-erythroid (BFU-E) and the colony-forming unit-erythroid (CFU-E) stages. BFU-Es are progenitor cells that in culture produce bursts or clusters of erythroid colonies, are relatively less sensitive to erythropoietin, and are more plastic with respect to important gene expression parameters, such as the synthesis of adult or fetal hemoglobin (HbF) by their descendants. CFU-Es produce single colonies, exhibit considerably higher sensitivity to erythropoietin, and appear to be more fixed in their potential to express a particular subset of globin genes. CFU-Es appear to give rise to the first morphologically recognizable erythroid cells, the proerythroblasts. At this "primitive" morphologic stage, the program of erythroid cell expression has already been essentially predetermined. The cell is predestined to undergo only a limited additional number of cell divisions, culminating in formation of the enucleate reticulocyte. The terminal maturation stages are morphologically recognizable as erythroblasts exhibiting progressive hemoglobinization of the cytoplasm, condensation and eventual ejection of the nucleus, and remodeling of the plasma membrane. Actual expression of the preprogrammed genes occurs during the 5- to 7-day period of erythroblast maturation.

As discussed in Chapter 24, the actual reconfiguration of chromatin for activation of the genes and activation itself appear to require the concerted and complex interaction of a diverse but limited group of transcription factors and associated epigenetic regulators. These regulatory proteins recognize a specific array of promoter and enhancer sequences that are embedded as recurrent motifs in and around the appropriate target genes. Even though an enormous amount of information has been gathered about sequences such as the GATA enhancers and their cognate transcription factors (e.g., GATA, FOG, ETS), the precise means by which these sequences and factors cause erythroid differentiation remains mysterious. At this time, this information is of limited clinical relevance to anemias or polycythemias. The orderly 14- to 21-day sequence of differentiation and maturation becomes progressively influenced by the levels of erythropoietin available to the progenitor cells, possibly because of increasing density and affinity of erythropoietin receptors on their cell surfaces. Within 24 hours after enucleation, the reticulocyte traverses the bone marrow–blood barrier membrane and enters the circulation as an immature erythrocyte. These cells retain remnants of nucleated precursors in the form of a relatively small number of polyribosomes actively translating messenger RNA (>90% of which is globin messenger RNA), a cell membrane that retains some molecules and structures reminiscent of its earlier stages of differentiation, and the complement of enzymes, phospholipids, and cytoskeletal proteins that the cell will possess throughout its remaining lifespan.

During its first 24 hours in the circulation, the reticulocyte spends considerable amounts of time in the spleen, during which its membrane is "polished." This is a poorly understood remodeling process

by which some lipids and proteins, including adhesive molecules such as fibronectin, are removed. The content of polyribosomes and other nucleic acids progressively declines so that stainability with methylene blue is lost by the end of the first day. At this time, the RBC is regarded as a mature erythrocyte, and it circulates largely unchanged for the remainder of its 120-day lifespan.

Perhaps the most remarkable feature of the human RBC is its durability, given that it is an enucleated cell devoid of organelles that appear to be critical for the survival and function of most other cell types. The RBC has no mitochondria available for efficient oxidative metabolism; no ribosomes for regeneration of lost or damaged proteins; a very limited metabolic repertoire that largely precludes de-novo synthesis of lipids; and no nucleus to direct regenerative processes, adaptation to circulatory stresses, or cell division to replenish itself. Given these handicaps, the 120-day survival of these cells is even more striking considering the multiple and often exceedingly hostile environments they must traverse. Mechanical stresses of the circulation include high hydrostatic pressure and turbulence and the shear stresses inherent in a microcirculation networked with many capillaries having diameters only one-third to one-half that of the normal RBC. Biochemical stresses include osmotic and redox fluxes associated with travel through the collecting system of the kidney; the sluggish vascular beds of the spleen, muscle, and bone; and the rapid changes in ambient oxygen pressures occurring in the lungs. All conspire to damage RBCs. Their 4-month survival is truly remarkable.

The ability of the RBC to persist in the circulation depends on its simple but exquisitely adaptive membrane structures; its pathways of intermediary energy metabolism and redox regulation; and its ability to maintain its largest cytoplasmic component, hemoglobin, in a soluble and nonoxidized state. The membrane and enzymes of the RBC appear to be exquisitely crafted to protect the cell from the external ravages of the circulation and the potential internal assaults of the massive amount of iron-rich and potentially oxidizing protein represented by its complement of hemoglobin molecules. For these reasons, a few basic features of these membrane and enzyme systems merit comment before considering the hemoglobin molecule itself.

MAJOR FEATURES OF THE RED BLOOD CELL MEMBRANE

Chapter 43 describes the RBC membrane in considerable detail using it as a model for understanding membrane structure in general. Only a few major aspects of that discussion bear repeating for the purposes of this chapter. The RBC membrane and its underlying cytoskeleton have evolved to provide mechanical strength and the necessary pliability and resilience to withstand the mechanical, osmotic, and chemical stresses of the circulation. Because the lipid bilayer membrane essentially has the physical properties of a soap bubble, it would rapidly be emulsified in the circulation. Strength and order are provided to the lipid bilayer by the hexagonal arrays of the highly helical protein spectrin, which forms a latticework underlying the membrane.

The spectrin meshwork is held together by adaptor molecules, such as protein 4.1, adducin, p55, and ankyrin, arrayed at defined points along the highly coiled, rodlike structure of the spectrin oligomers. These protein–protein interactions appear to be critical for holding the latticework together in what has been described as the "horizontal" dimension that permits resistance to shear stress. The involvement of intermediate-length actin fibers and the variability of binding affinities by phosphorylation state appear to provide some flexibility and pliability at these points of interaction. Strength in the "vertical" dimension is provided by additional molecules or additional binding functions of the same molecule, whereby the latticework is attached to the lipid bilayer. For the most part, the physiologically important attachments appear to be indirect. Linkage is mediated through the interaction of the adaptor proteins, such as ankyrin and protein 4.1, with the cytoplasmic domains of abundant transmembrane proteins. These proteins traverse and are embedded in the lipid bilayer, providing a firm anchor. The two most critical of these molecules appear to be band 3 (i.e., the anion transport channel) and a glycophorin, probably glycophorin C/D. A possible additional stabilizing role for the Rh protein complex has been suggested. The construction of these attachments by multiple "hinge" or coupling molecules appears to provide for the flexibility and distensibility of the RBC membrane, a property essential to its ability to flow through small capillaries.

As described in Chapter 43, the complex structure of the membrane is exquisitely sensitive to perturbations impinging on any of its components. In particular, the membrane cytoskeleton and phospholipid structures are each highly susceptible to oxidation, particularly by partially proteolyzed molecules of hemoglobin, which denature to form highly toxic compounds called *hemopyrroles*. This interaction of denatured hemoglobin with the RBC membrane is clinically important, as illustrated by its impact on the pathophysiology of sickle cell anemia (see Chapter 40) or of oxidized and precipitated globin inclusion bodies in thalassemia. In this chapter, it is sufficient to note that alterations of proteins of the RBC membrane can contribute to shortening the lifespan of the RBC. Damage can result from direct defects in the cytoskeletal proteins themselves or from susceptibility of these proteins to direct oxidation or attack by oxidized or denatured hemoglobin molecules. Readers are referred to the aforementioned chapters for detailed descriptions of the relevant phenomena.

ENZYMES OF RED BLOOD CELL INTERMEDIARY

Metabolism

Mammalian erythrocytes possess a highly specialized but remarkably simplified set of metabolic pathways. As discussed in Chapter 42, there are essentially three relevant sets of pathways. The first two are interconnected by the enzyme glucose-6-phosphate dehydrogenase (G6PD). Glucose entering the RBC is metabolized by an anaerobic pathway, the Embden-Meyerhof pathway, which terminates with the enzyme lactic dehydrogenase, forming lactate. Despite its inefficiency (a net of only two adenosine triphosphate [ATP]/glucose molecule), this pathway is the sole source of usable ATP in the cell. Moreover, the pathway generates reduced nicotinamide adenine dinucleotide (NADH), a molecule necessary for driving the reduction of methemoglobin to hemoglobin (see Chapter 41). A shunt within this pathway, the Rapoport-Luebering shunt, generates the compound 2,3-bisphosphoglycerate (bis[phosphoglyceric acid]) (2,3-BPG), an important cofactor that, when bound to hemoglobin, reduces the affinity of hemoglobin for oxygen (see Hemoglobin Function). The ATP generated is necessary for kinase reactions controlling phosphorylation of membrane and signaling components, for fueling ion pumps and channels, and for maintaining phospholipid levels.

The anaerobic metabolic pathway generates, as one of its intermediates, glucose-6 phosphate, which is the substrate for G6PD. G6PD appears to be the rate-limiting enzyme for a linked pathway called the *oxidative hexose monophosphate shunt*. This pathway involves a cascade of reactions culminating in the reduction of oxidized glutathione to reduced glutathione. Reduced glutathione is used to reverse oxidation of critical structures, including hemoglobin, cytoskeletal proteins, and membrane lipids. Anaerobic glycolysis generates NADH for methemoglobin reduction, 2,3-BPG for modulation of hemoglobin oxygen affinity, and ATP for metabolic energy requirements. Its end product is lactate. The oxidative glycolysis pathway generates nicotinamide adenine dinucleotide phosphate (NADPH) and reduced glutathione for use as the major erythrocyte antioxidant.

During the past decade, most of the enzymes (or at least the erythroid isoforms of these enzymes) involved in RBC intermediary metabolism have been characterized at the molecular level by cloning of their cDNAs, genomic loci, or both. Some of the more relevant information arising from this progress is discussed in Chapter 42. The erythrocyte possesses membrane-based signaling receptors and cytoplasmic signal transduction elements similar, although perhaps

less elaborate, than those of nucleated cells. The relevance of these systems to the pathophysiology of RBC disorders is just becoming apparent.

RED BLOOD CELL SENESCENCE AND DESTRUCTION

Erythrocytes, despite their impressive adaptations to circulatory stresses, eventually wear out and are destroyed. RBC survival in humans appears to be remarkably uniform under normal circumstances, spanning approximately 120 days from release of the reticulocyte into the circulation to sequestration of the senescent RBC in the reticuloendothelial cells of the liver and spleen. The precise signal, or signals, marking RBCs for destruction remain unknown, as does the underlying pathophysiology within the RBC or on its surface. However, several interrelated theories have emerged; these are discussed only briefly because they are mentioned in other chapters.

Red blood cells accumulate surface blemishes during their lives in the circulation. These appear to result in part from the accumulation of small amounts of oxygen damage to membrane structures. The altered regions are sensed by the reticuloendothelial cells during passage of the erythrocytes through the liver and spleen. Removal or pitting of these damaged regions from RBC membranes can be documented microscopically; small amounts of normal membrane are also lost during the process.

The biconcave disk shape of the RBC, so important to its distensibility, depends on a high ratio of surface area to volume. This requires redundant membrane surface area. The membrane surface area of the normal biconcave disk is approximately 140 μm^2. To enclose a sphere containing a normal RBC volume (≈90 fL), only approximately 95 μm^2 would be needed. Progressive loss of membrane surface by means of the pitting phenomenon should ultimately cause the aging erythrocyte to assume a more rigid spherical shape. A sphere is inevitably far less distensible and far less capable of passing through small apertures than a disk, especially in the sluggish and torturous circulation of the spleen. This geometric mechanism can lead to the eventual destruction of the RBC.

Red blood cells progressively lose some of the critical enzymes needed for intermediary metabolism and antioxidant capacity. G6PD levels, for example, progressively decline during the circulating lifespan, as do levels of several other enzymes. The decline of certain enzymes can be used as a crude means of estimating the relative age of different RBC populations. The biochemical or oxidative mechanism of destruction postulates that aged RBCs are eventually depleted of critical enzymes needed for maintenance of redox status. Oxidation of critical membrane proteins, lipids, and hemoglobin would then ensue, causing distortion and rigidity of the RBC membrane, with accelerated loss as previously described. The end product would be spherocytes incapable of traversing the splenic vascular bed and escaping engulfment by the reticuloendothelial cell.

It has been proposed that an immune-type mechanism can contribute to normal and pathologic RBC senescence. This hypothesis is based on the observation that oxidative damage, regardless of cause, promotes a clustering, or *capping,* of oligomers of band 3 on the RBC surface. Under normal circumstances, band 3 molecules form monomers, dimers, or tetramers. Higher order aggregates appear to be recognized by an endogenous isoantibody possessed by all people. Any RBC accumulating oxidative damage from wear and tear in the circulation, from depletion of enzymes, or from internal pathologic processes such as denaturation of hemoglobin in certain hemoglobinopathies can accumulate these aggregates. The aggregates would then be bound by antibody and be removed by the reticuloendothelial cells as antigen–antibody complexes, using the same means used by reticuloendothelial cells to recognize any immune complex. This mechanism could also provide for the pitting or polishing of damaged RBC membranes. All three of the proposed mechanisms are interrelated by their inception with oxidative damage.

Other membrane-related changes might influence RBC destruction. Bcl-X_L, a suppressor of apoptosis, is present in erythrocyte membranes, and its antagonization may promote cell death. This may be mediated by calcium accumulation and phosphatidylserine exposure. Cholesterol and fatty acids accumulate on the aging RBC membrane and might be targets for oxidation induced by reactive oxygen species. RBCs are removed from the circulation by splenic macrophages, probably by several mechanisms. SHPS-1, a surface glycoprotein and a member of the immunoglobulin superfamily that interacts with RBC membrane CD47, is abundant in macrophages. Studies using mice expressing a mutant SHPS-1 suggested that this molecule might negatively regulate phagocytosis, influencing cell lifespan. Increasing phosphatidyl serine exposure and reduced aminophospholipid translocase activity during aging might induced oxidative damage to the cell. It is probable that these mechanisms leading to cell destruction are not mutually exclusive, that no single effect predominates, and that these events occur at different times at different sites of RBC damage.

Regardless of the mechanism(s) fostering eventual senescence and destruction of RBCs, the process itself involves components clinically useful for assessment of anemias associated with accelerated destruction. Chief among these is the generation of indirect or unconjugated bilirubin, the byproduct of heme catabolism occurring within the reticuloendothelial cells. In markedly accelerated states of RBC destruction, hypertrophy of the liver and spleen can also occur, providing a useful physical indicator of hemolytic anemia. These indirect clinical features, coupled with the reticulocyte count, remain more useful for detecting clinical hemolysis than complicated studies of RBC kinetics.

HEMOGLOBIN SYNTHESIS, STRUCTURE, AND FUNCTION

Basic Features

Hemoglobins are the major oxygen-carrying pigments of the body. They are packaged into RBCs in quantities sufficient to carry enough oxygen from the lungs to the tissues to meet the needs of those cells for oxidative metabolism. These quantities are enormous—almost 2 lb of hemoglobin are present in the body of a reasonably sized human at any given time. Because free hemoglobin in the bloodstream is catabolized and excreted renally in a matter of minutes, packaging in erythrocytes is essential to preserve the newly synthesized molecules for the entire 4-month lifespan of the RBC. Otherwise, the caloric and biosynthetic resources needed to replace daily losses of hemoglobin would be prohibitive. The RBC's major function is to encase hemoglobin and protect it so it can function as an oxygen transporter for a prolonged period. An additional function of hemoglobin is to modulate vascular tone by its transport of nitric oxide (NO) and possibly nitrous oxide.

The cellular content of blood influences its viscosity; in particular, the hemodynamics are adversely compromised by the presence of too many circulating erythrocytes because blood viscosity correlates especially with hematocrit. To provide for adequate oxygen transport (i.e., enough hemoglobin molecules) in a number of RBCs compatible with tolerable viscosity, each cell must enclose a high concentration of hemoglobin (32-35 g per 100 mL of cytoplasm). This concentration is close to the solubility limit of hemoglobin in physiologic solutions. It follows that even minor perturbations within these molecules (e.g., oxidation) or in the milieu (e.g., changes in pH or ionic strength) can have potentially devastating effects on the solubility of hemoglobin. Because polymerized or precipitated hemoglobins derange intracellular viscosity, trigger proteolytic reactions that lead to oxidative damage of erythrocytes, and compromise oxygen transport, it is not surprising that the fate of the RBC is inextricably interwoven with the state of its enormous complement of hemoglobin molecules.

Hemoglobin Structure

The hemoglobin tetramer consists of two pairs of unlike globin polypeptide chains, each associated with a heme group. Normal

hemoglobin has two α- and two non–α-globin chains; the interaction of these chains is responsible for the quaternary structure of the hemoglobin molecule and normal oxygen transport. Functionally, the second exon of each globin gene encodes the major component of the heme-binding pocket, and the α and non-α contacts are regulated by the third exon.

The behavior of hemoglobin is determined by its primary structure, the covalent linking of amino acids to form the polypeptide globin. The higher order structures of hemoglobin depend on the sequence of amino acid residues that make up the globin chain. The α-globin chains contain 141 residues, and the β-globin–like chains are 146 amino acids long (Fig. 31-1). There is considerable homology among these globins, especially among the non–α-globin chains. Whereas the α-globin genes *(HBA2, HBA1)* result from a very ancient gene duplication, the non–α-globin genes *(HBE, HBG2, HBG1, HBD, HBB)* are the result of more recent gene duplications and are more akin to each other than they are to the α-like globin genes. Gene conversion events also ensure the similarity of duplicated genes.

Elements of the secondary structure of globin are shown in Figs. 31-1 and 31-2. Approximately 75% of the globin polypeptide chain forms an α-helix. There are eight helical segments, A through H, separated by short stretches from which the α-helix is absent. These nonhelical segments permit folding of the polypeptide on itself and are often dictated by the presence of prolyl residues, which are generally unable to participate in the formation of α-helices. Although the helical segments of the α- and non–α-globin chains do not exactly correspond, it is possible to align amino acid residues in all globin peptides by their helical and nonhelical residue numbers, as indicated in Fig. 31-1. This permits greater appreciation of the homology among globins. Some of the amino acids of globin are invariant, or conserved, in the sense that they are preserved during phylogeny. These residues occur at portions of the molecule that are critical for its stability and function, such as heme binding residues, hydrophobic amino acids of the interior of the molecule, and certain subunit contacts at the α_1–β_2 interface. The introduction of prolyl residues into α-helical segments by mutation leads to interruption of the α-helix and instability of the resulting hemoglobin molecule.

The poorly understood laws that govern the folding of proteins are responsible for the tertiary structure of globin, shown in Fig. 31-2. This folding pattern places polar residues exteriorly and provides a hydrophobic niche for the heme ring between the E and F helices. Numerous noncovalent bonds are formed between the heme and surrounding amino acid residues of globin. An iron atom in the center of the porphyrin ring forms an important bond with the F8 or proximal histidine and through the linked oxygen with the E7 or distal histidine residue. Oxygenation and deoxygenation of hemoglobin occur at the heme iron. Folding of globin and association of chains into dimers and tetramers was once thought to occur spontaneously. However, it is now clear that these processes are assisted by chaperone proteins, which are described in Chapters 4 and 5.

Two α-globin chains and two non–α-globin chains fit together specifically to form a hemoglobin tetramer with a molecular mass of approximately 64,000 daltons and with the quaternary structure shown in Fig. 31-3. The motion of individual globin chains, as well

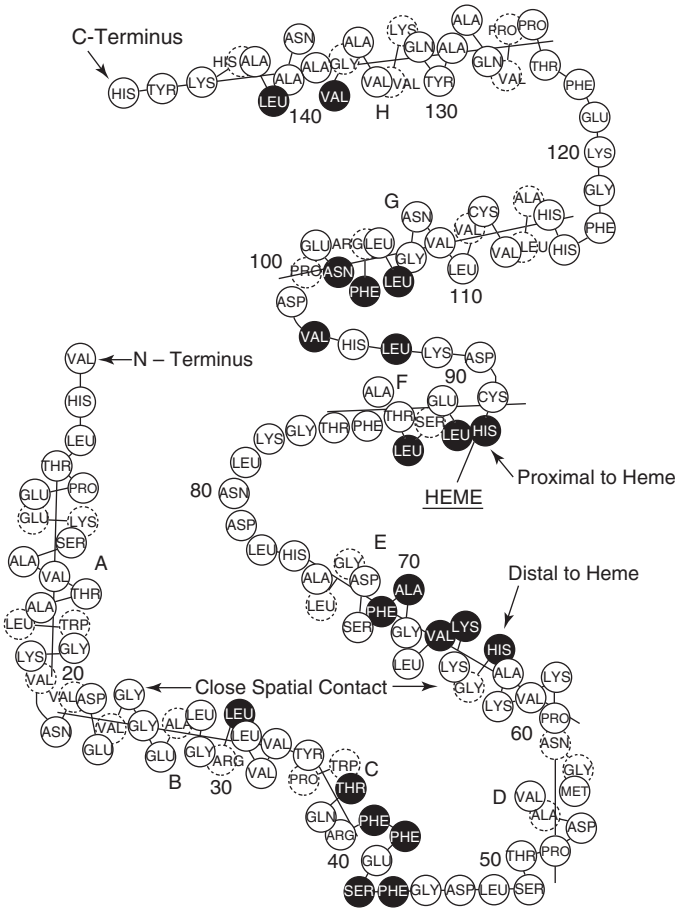

Figure 31-1 THE β-GLOBIN CHAIN SHOWING HELICAL AND NONHELICAL SEGMENTS. The helical segments are labeled A through H, and the nonhelical segments are designated NA for residues between the N terminus and the A helix, CD for residues between the C and D helices, and so forth. *(From Huisman THJ, Schroeder WA:* New aspects of the structure, function, and synthesis of hemoglobin. *Boca Raton, 1971, Fl, CRC Press.)*

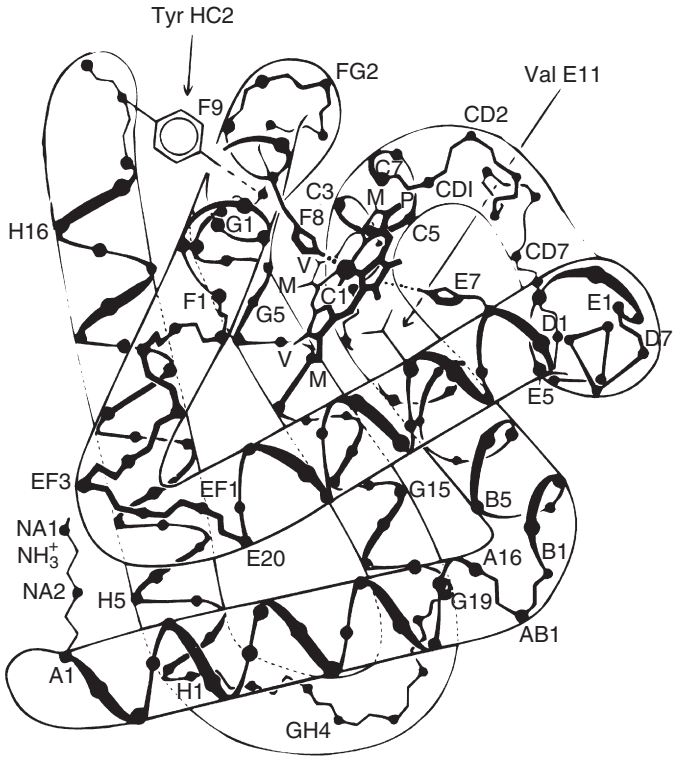

Figure 31-2 TERTIARY STRUCTURE OF A GLOBIN CHAIN. Globin folds into a tertiary structure such that polar or charged amino acids are located on the exterior of the molecule and the heme ring resides in a hydrophobic niche between the E and F helices. Linked to the heme are the proximal (F8) histidine and the distal (E7) histidine. *(From Perutz MF: Molecular anatomy, physiology, and pathology of hemoglobin. In Stamatoyannopoulos G, Neinhuis AW, Leder P, et al, editors:* The molecular basis of blood diseases. *Philadelphia, 1987, Saunders, p 127.)*

as the movement of globin chains relative to each other during oxygenation and deoxygenation, gives hemoglobin its unique usefulness as a respiratory protein.

Hemoglobin Function

Evolution has honed the hemoglobin tetramer into a molecule ideally suited for its tasks. Because human hemoglobin must behave differently than that of altitude dwelling species or species inhabiting hypoxic locales, many different variants of the same basic molecular design have evolved. Because of the exigencies of molecular evolution, we find in the genome of all animals, including humans, attempts by nature to propagate a variety of different globin genes. The crystallographic studies of Perutz and coworkers defined the oxygenated and deoxygenated structures of hemoglobin at Ångström-unit resolution and provided an exquisitely detailed picture of how the globin chains and individual amino acid residues respond to the loading and unloading of oxygen. All of these, however, share the properties of highly reversible oxygen binding and high solubility in cytoplasm. We know more about the function of hemoglobin than about virtually any other protein, and the knowledge of this mechanism provides a beautiful and intellectually satisfying culmination to decades of study by many investigators.

The oxygen dissociation curve of hemoglobin, shown in Fig. 31-4, describes the percent saturation of hemoglobin with oxygen at different oxygen tensions. The sigmoidal shape of this curve is a result of interaction among the subunits of hemoglobin. Communication within the tetramer is called heme–heme interaction or cooperativity. This implies that the four heme groups do not undergo simultaneous oxygenation or deoxygenation but rather that the state of each heme unit with regard to the presence or absence of bound oxygen influences the binding of oxygen to other heme groups. Myoglobin, a heme-containing protein with virtually the same tertiary structure as globin, exists in muscle as a monomer. The oxygen equilibrium curve of myoglobin is a rectangular hyperbola; in physiologic terms, it rapidly becomes fully saturated at low oxygen tensions and remains saturated as the oxygen tension plateaus. The difference in the oxygen equilibrium curves of myoglobin and hemoglobin lies in the tetrameric nature of the hemoglobin molecule and the cooperativity permitted by the association of similar but unlike subunits. Compared with hemoglobin, myoglobin has a very low P_{50} (i.e., oxygen partial pressure at which the molecule is one-half saturated). It therefore has an extremely high oxygen affinity and would not be useful for delivering oxygen to tissues. The oxygen in myoglobin is passed on to the mitochondria, where oxidative metabolism occurs. The sigmoidal shape of the oxygen dissociation curve of hemoglobin indicates that the totally deoxygenated hemoglobin tetramer is slow to become oxygenated, but as oxygenation proceeds, the reaction of heme with oxygen accelerates. Perutz has drawn an analogy in which the "appetite" of heme for oxygen grows with the "eating," and conversely, loss of oxygen by heme lowers the oxygen affinity of the remaining heme groups. The Hill coefficient, *n,* which can be calculated from plots of oxygen equilibrium curves, is a description of heme–heme interaction or cooperativity that explains in part the oxygen-binding properties of hemoglobin and myoglobin. The Hill coefficient for myoglobin is 1, indicating no cooperativity; *n* is approximately 3 for the normal human hemoglobin A molecule.

The oxygen affinity of hemoglobin within the erythrocyte does not depend solely on the intrinsic properties of the tetramer. The position of the hemoglobin oxygen dissociation curve, and therefore the P_{50}, can be influenced by a number of heterotropic modifiers,

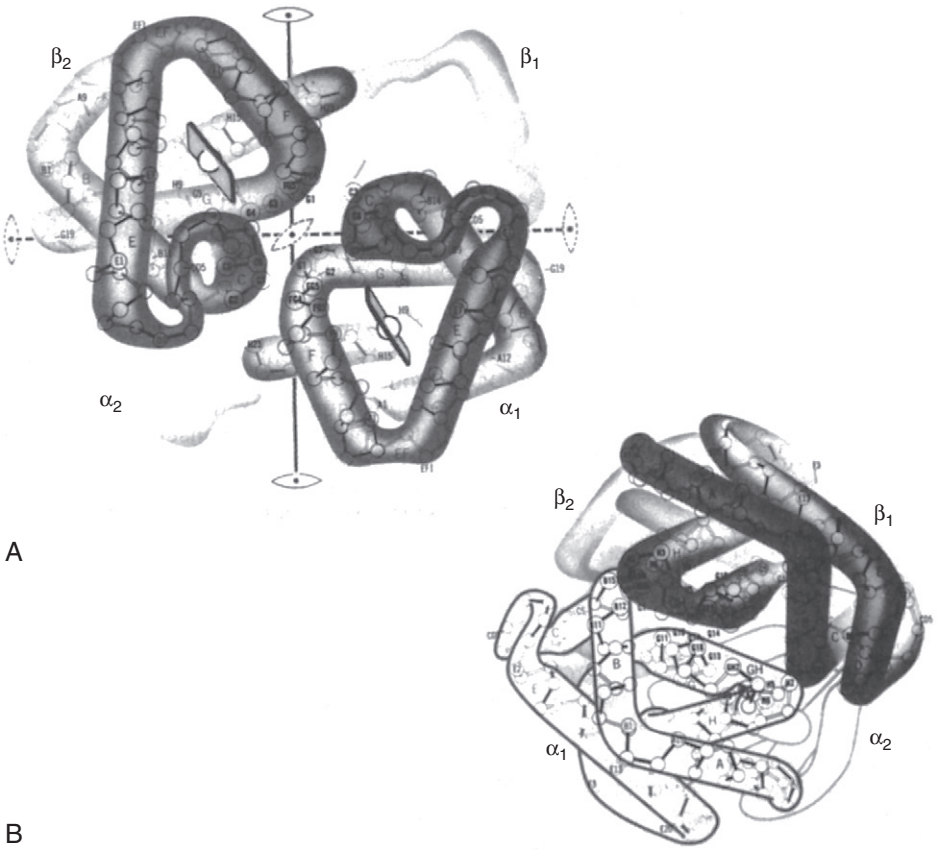

Figure 31-3 QUATERNARY STRUCTURE OF HEMOGLOBIN. The contacts between subunits are shown as circled amino acids. In the front view **(A),** α_1–β_2 contacts are shown, and in the side view **(B),** α_1-β–β_1 contacts are depicted. *(From Dickerson RE, Geis I:* Hemoglobin: Structure, function, and evolution pathology. *Menlo Park, Calif, 1983, Benjamin-Cummings.)*

including temperature, pH, and small organic phosphate molecules in the cell. The effects of these modifiers on P_{50} are shown in Fig. 31-4.

Hemoglobin is the prototype of an allosteric protein; its structure and function are influenced by other molecules. The major intracellular modulator of hemoglobin–oxygen affinity in human erythrocytes is 2,3-BPG, an intermediate product of glycolysis that is present within the erythrocyte at concentrations equimolar to hemoglobin. The synthesis of 2,3-BPG is enzymatically regulated, and its levels can change depending on the conditions extant. 2,3-BPG is able to bind stereospecifically within the central cavity of the hemoglobin tetramer. Hemoglobin prepared in the absence of 2,3-BPG has a very high oxygen affinity, but as 2,3-BPG is added to a hemoglobin solution, the oxygen affinity progressively decreases. 2,3-BPG is a polyanion that binds strongly to the deoxygenated form of hemoglobin but poorly to its oxygenated or other liganded forms. Specific amino acids are involved in the binding of 2,3-BPG; these β-chain residues include the N-terminal valines, the H21 histidine (position 143), and the EF6 lysine (position 82). In oxyhemoglobin, the H helices of the β-chains are insufficiently spread to permit firm binding of 2,3-BPG; this, along with other conformational changes, favors the binding of this anion to the deoxygenated rather than the oxygenated form of hemoglobin. The binding of 2,3-BPG stabilizes the T (tense) structure of the deoxygenated form at the expense of the R (relaxed) structure of the oxyhemoglobin tetramer.

Transition from the deoxy (T) to the oxy (R) form of hemoglobin is accompanied by rotation of the αβ dimers along the α_1–β_2 contact region (Fig. 31-5). The T structure is stabilized by salt bridges, which are broken as the molecule switches into the R structure. Some abnormal hemoglobins with an intrinsically high oxygen affinity, or low P_{50}, occur as a result of an amino acid substitution that leads to loss of bonds that stabilize the tetramer in the T conformation. Hydrogen ions, chloride ions, and carbon dioxide all decrease the affinity of hemoglobin for oxygen by strengthening the salt bridges that lock the molecule into its T conformation. The corollary of the lowering of hemoglobin oxygen affinity by protons is the combination of hemoglobin with protons on deoxygenation. This is known as the Bohr effect and is responsible for carbon dioxide transport in blood, another critical function of the hemoglobin molecule. Deoxyhemoglobin binds the hydrogen ion liberated by the reaction of carbon dioxide with water, increasing the concentration of bicarbonate. Within the lungs, hydrogen ions are lost as hemoglobin binds oxygen; therefore, carbon dioxide leaves solution and is excreted from the body through the lungs. Deoxyhemoglobin can also directly bind carbon dioxide; however, this process involves the minority of carbon dioxide exchanged by the RBCs.

Red blood cells containing high levels of hemoglobin F have high oxygen affinity because it binds 2,3-BPG poorly. Physiologically, this predicts that the hemoglobin of fetuses should be oxygenated at the expense of the maternal hemoglobin A. The high oxygen affinity of hemoglobin F is accounted for by a single change in its primary structure, the presence of a serine residue at helical position H21 in place of the histidine found in the β-globin chain. This weakens the binding of 2,3-BPG and leads to stabilization of the molecule in its R state.

Interactions of hemoglobin with NO have been a recent focus of investigation. NO, generated from L-arginine by nitric oxide synthases, activates soluble guanylate cyclase to produce the second messenger cyclic guanosine monophosphate (cGMP). As a potent vasodilator, NO is an important regulator of vascular tone. The reaction of free NO with erythrocytes is diffusion limited. Normally, the primary NO–hemoglobin adduct is nitrosyl (heme) hemoglobin

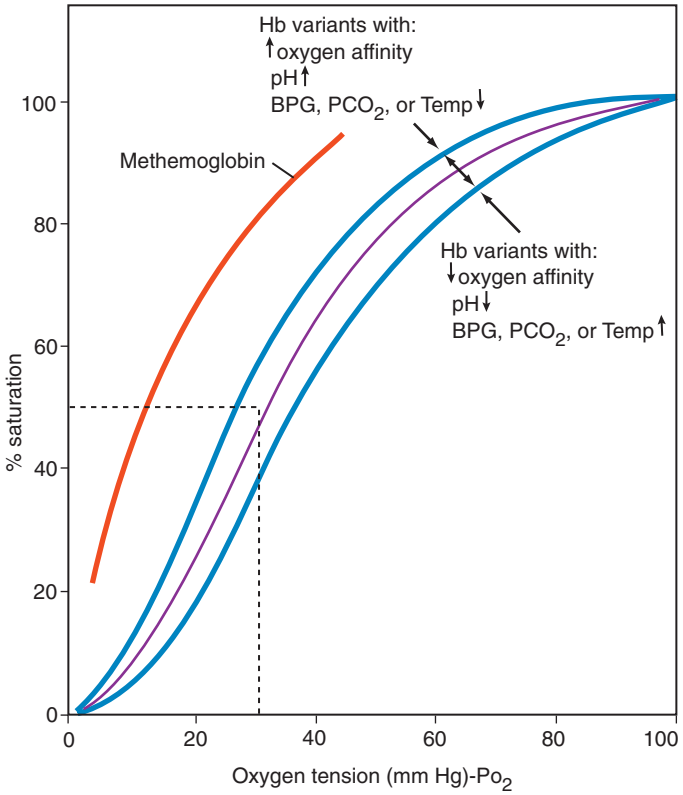

Figure 31-4 OXYGEN DISSOCIATION CURVE OF HEMOGLOBIN. The percent saturation of hemoglobin with oxygen at different oxygen tensions is depicted by the *red sigmoidal curve*. The P50 (i.e., oxygen tension at which the hemoglobin molecule is one-half saturated) is approximately 27 mm Hg in normal erythrocytes *(dotted lines)*. Heterotopic modifiers of hemoglobin function can shift the curve leftward by increasing or rightward by decreasing its oxygen affinity. *PCO_2,* Partial pressure of carbon dioxide; *Po_2,* partial pressure of oxygen. *(From Benz EJ, Jr: Synthesis, structure, and function of hemoglobin. In Kelly WN, DeVita VT, editors:* Textbook of internal medicine, *vol 1. Philadelphia, 1989, JB Lippincott, p 236.)*

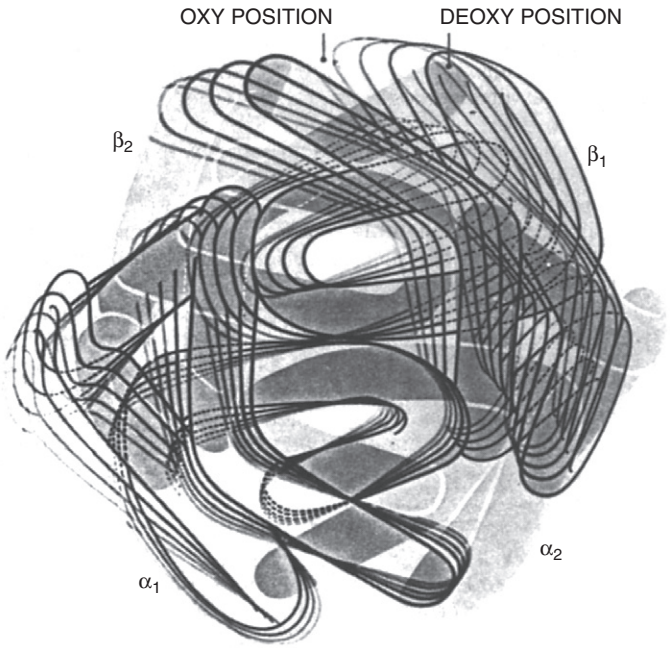

Figure 31-5 SUBUNIT MOTION IN THE HEMOGLOBIN TETRAMER. The relative motion of hemoglobin subunits on oxygenation and deoxygenation is shown. The $\alpha_1\beta_1$ dimer *(black)* is moving relative to the $\alpha_2\beta_2$ dimer *(shaded)*. The oxyhemoglobin tetramer (R state) is more compact than the deoxyhemoglobin configuration (T state). *(From Dickerson RE, Geis I:* Hemoglobin: Structure, function, and evolution pathology. *Menlo Park, Calif, 1983, Benjamin-Cummings.)*

(HbFe[II]NO). Within the erythrocyte, β93 cysteine is reduced and seems incapable of NO storage and delivery by *S*-nitrosohemoglobin as originally proposed. NO was thought to form *S*-nitrosylhemoglobin in the lungs, where hemoglobin is in its R or oxygenated state, and liberate NO in the microcirculation, where the transition of the R to T conformation induced by deoxygenation released NO from hemoglobin. However, studies suggest that NO binding to heme groups is physiologically a rapidly reversible process. This view supports a model of hemoglobin delivery of NO distinct from its dissociation from the β93 cysteine residues. Small nitrosothiol molecules could also be involved in NO transfer. The thiol groups of hemoglobin can exchange NO with small nitrosothiols derived from free cysteine and glutathione. Accordingly, the thiol groups of hemoglobin could bind and transfer NO or exchange NO with small shuttle molecules, increasing perfusion of hypoxic tissues. It has been suggested that cytoskeletal and other erythrocyte proteins slow NO influx into the cell and, coupled with NO heme binding, preserve NO bioactivity. NO–hemoglobin interactions, whether through *S*-nitrosohemoglobin formation at the β93 cysteine or the formation of nitroso intermediates, are likely to be physiologically important. Hemoglobin liberated from the intravascularly hemolyzed RBCs rapidly inactivates NO. As the RBC lyses, arginase is also released and destroys the substrate for NO synthases, L-arginine. Together, this leads to a reduction in biologically active NO. With hemolysis as in sickle cell disease or thalassemia, reduced NO bioavailability is associated with disease complications such as pulmonary hypertension, leg ulcers, priapism, and perhaps increased risk of stroke. Lactic dehydrogenase also released from the RBC in hemolytic anemia is an excellent marker of these complications.

In summary, the primary amino acid structure of α- and non–α-globin chains dictates the inevitable quaternary structure in which resides the ability of hemoglobin to serve as a respiratory protein. Cooperativity ensures rapid binding of oxygen in the lungs and unloading in tissues. Similarly, carbon dioxide is transported from tissues to lungs. The function of hemoglobin may be influenced by mutation and by heterotropic effectors such as protons and 2,3-BPG. The molecule itself changes shape as it provides oxygen for metabolism; it is a lung in miniature, breathing as it allows the body to respire.

Globin Gene Clusters

The amounts and types of human hemoglobin produced at any given age are determined primarily by the selective expression of the individual genes encoding each globin chain. The globin genes of humans are located in two clusters (Fig. 31-6): α-like genes in approximately 30 kb of DNA on the short arm of chromosome 16 between band p13.2 and the telomere and β-like genes in approximately 70 kb of DNA on the terminal portion of the short arm of chromosome 11 (p15). Each gene shares certain basic organizational features. Each contains three exons separated by two introns. Both introns of the α-gene are small (100-300 bp); non–α-genes have one small and one large (1000-1200 bp) intron. The second exon of each globin gene encodes the major components of the heme-binding pocket, and the third encodes the α- and non-α contact points.

Flanking each gene at the 5′ and 3′ ends are groups of conserved nucleotides. In conjunction with protein factors, these influence the promotion of gene transcription, ensure the fidelity of the transcript and its translatability, specify sites for the initiation and termination of translation, and improve the stability of the newly synthesized mRNA (Fig. 31-7). Also encoded within the genes are signals that permit the enzymatic machinery within the nucleus to excise precisely the introns from the mRNA precursor and splice together the exons to form a contiguous "mature" mRNA. The spliced mRNA is transported to the cytoplasm and translated into protein. These conserved signals lie at the junction of the exon and intron and within the introns themselves. They are recognized by small nuclear ribonucleoprotein (RNP) particles, which participate in the formation of a spliceosome, or splicing complex. Their preservation is critical for the splicing process to occur. When mutations occur within splice signal sites, globin synthesis is often impaired. The 5′ end of the mRNA contains a cap structure, and the 3′ end contains a poly(A) tail, as described in Chapter 1.

Conserved nucleotide clusters 5′ to the coding portion of each globin gene in aggregate act as promoters (see Fig. 31-7). Globin promoters are modular. Some modules are located relatively close to the initiation site of mRNA translation, and some are more distally placed. Promoters ultimately form the binding sites for the RNA polymerase complexes that catalyze gene transcription. Mutations within the promoter can affect the level of gene transcription and the amount of globin made. Surrounding and within each gene are other sequence elements that play important roles in its transcriptional regulation (see Fig. 31-6). These clusters, called *enhancers* and *silencers* (see Chapter 1), may lie within introns or 5′ and 3′ to the coding sequences; in some instances, they are quite remote from the gene. The higher order structure of DNA in chromatin may permit close approximation of these remote enhancers to the gene during transcription. Enhancers play important roles in the tissue-specific regulation of globin gene expression. Representative regulatory sequences

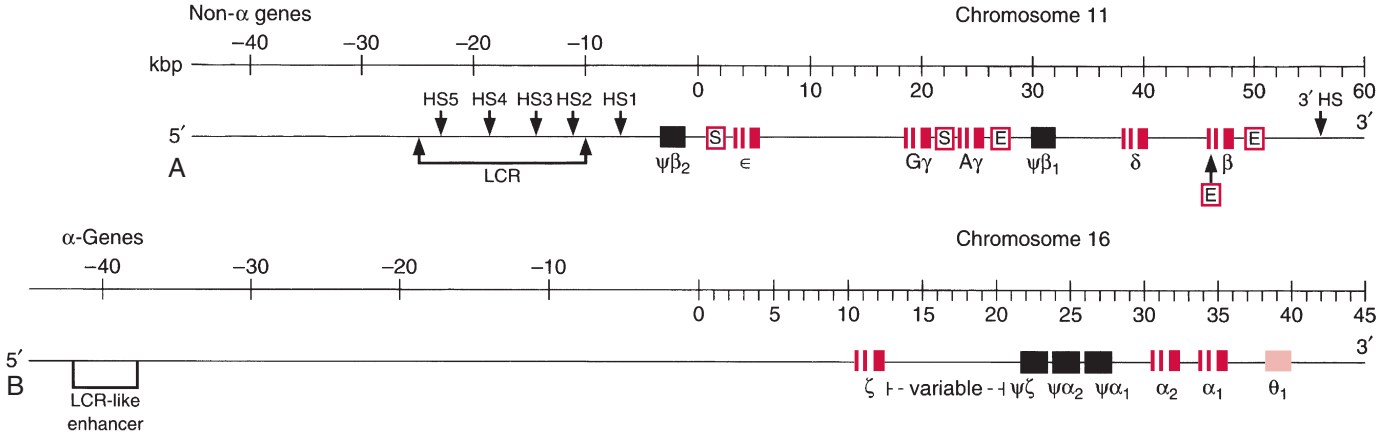

Figure 31-6 Maps of the β-like and α-like globin gene clusters located on chromosome 11 **(A)** and chromosome 16 **(B).** Within each gene cluster are pseudogenes, which are remnants of previously expressed globin genes that have become inactivated as a result of mutation. Active genes are shown in *red boxes* filled with clear introns; inactive or pseudogenes genes are shown in *solid boxes,* and the ζ-globin gene is shown as a *pink box*. Although this gene is transcribed, it is not clear whether it is represented in a cellular protein. The distance between the functional ζ-globin and pseudo-ζ-globin gene is variable because of the presence of repeated elements. *E,* Enhancer; *HS,* DNase hypersensitive site; *LCR,* locus control region; *S,* silencer.

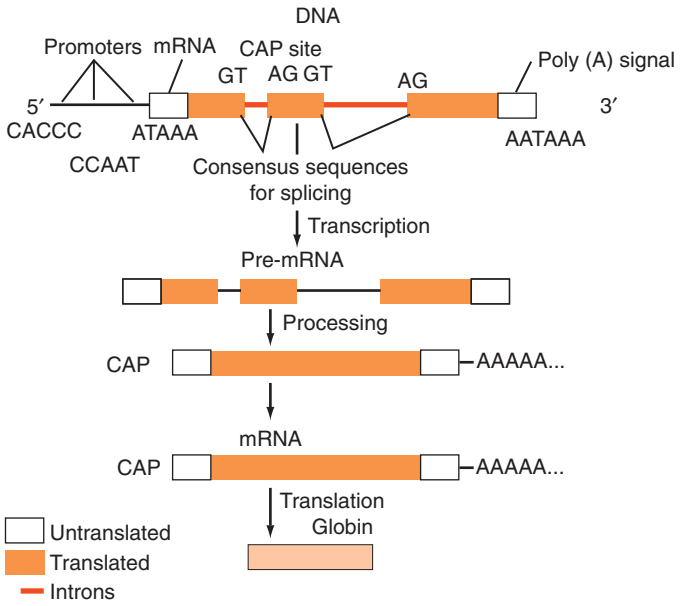

Figure 31-7 PATHWAY OF GLOBIN BIOSYNTHESIS. Transcription of the globin gene results in a large pre-mRNA molecule containing intervening sequences. During intranuclear processing of this molecule, the intervening sequences are excised and the coding sequences ligated to form a contiguous stretch of RNA, which codes for the globin protein. The message is further processed by the addition of a CAP and a poly(A) tail. The mature message is transported from the nucleus to cytoplasm, where it is translated on polyribosomes by the addition of activated amino acids to a growing polypeptide chain. Globin acquires heme and α: non-α dimers are formed and a hemoglobin tetramer is assembled. *(From Steinberg, MH: Hemoglobinopathies and thalassemias. In Stein JH, editor:* Internal medicine, *ed 4, St. Louis, 1994, Mosby-Year Book, p 852.)*

near the globin genes are shown in Fig. 31-6 (locus control region [LCR], LCR-like enhancer). DNA elements controlling globin genes are described in more detail later.

The α-like and β-like globin genes are ordered in the 5′ to 3′ direction in the same sequence expressed during embryonic, fetal, and adult development (Fig. 31-8). The functional significance of this arrangement is unclear. However, evidence suggests that the ordering of the ε, γ, δ, and β genes could be an important factor influencing the ability of each locus to interact with distant control elements at different developmental stages.

The α-like and β-like gene clusters probably are the result of an ancient duplication of a primordial globin gene that existed early in the history of vertebrates, approximately 500 million years ago. Each gene cluster probably developed from the duplication of ancestral genes and subsequent divergence through eons of evolution. Within the α-like gene cluster, the δ-globin gene is expressed only very early in embryogenesis and participates in the formation of embryonic hemoglobins. A μ, α-like globin gene *(HBM),* that codes for a 141 amino acid α-globin–like chain has been recently detected and is expressed in erythroid cells in a highly regulated fashion; however, an associated protein has not been found.

The α-globin genes are duplicated, a characteristic of most globin genes, and their encoded amino acid sequences are identical; therefore, only a single α-globin polypeptide results. Minor differences within the second intervening sequence and the 3′ flanking regions of the α-globin gene permit identification of transcripts from each gene. The 5′ or α_2-gene is expressed more efficiently than the 3′ or α_1-gene, so abnormalities of this gene are more likely to be clinically apparent. Both clusters contain genes that are actively transcribed, as well as pseudogenes whose defective structures prohibit expression at any time.

The gene 3′ to the α_1-gene is the Θ-gene, a somewhat mysterious element of the α-gene cluster. Although Θ-gene transcripts are found in fetal tissue and adult erythroid marrow, it is unclear whether this gene's translation product is able to participate in the formation of a functional tetramer. The Θ-globin protein has been found in vivo, but deletion of the Θ-globin gene does not appear to have any implications for developing fetuses. In vitro, Θ-globin mRNA is correctly spliced, and Θ-globin cDNA can direct synthesis of a translatable mRNA and a Θ-globin protein.

The β-like–globin gene cluster consists of the embryonic ε-gene, transcribed only during the first 6 to 11 weeks of life; the duplicated γ-globin genes that code for the dominant non–α-globin of fetal life; and the δ- and β-globin genes that code for the hemoglobins of adults. The coding sequences of the two γ-globin genes are identical, except at codon 136, where the 5′ or Gγ-gene codes for glutamic acid; the 3′ or Aγ-gene encodes an alanine residue. These genes are unequally expressed during fetal development. A switch in their relative rates of expression leads to a similar disparity between the amounts of Gγ and Aγ chains in adults. Although the Gγ/Aγ switch is interesting from the standpoint of the control of gene expression, it is of little clinical importance. Hemoglobin F in fetuses and adults contains a mixture of Gγ and Aγ chains; the functional qualities of these hemoglobins are identical.

The δ- and β-globin genes are probably the result of a duplication event that occurred more than 40 million years ago. The β-globin gene has become the predominant gene, coding for most non–α-globin chains of adults. The δ-globin gene has undergone mutation in several critical areas, and its expression is greatly curtailed. Its product, a minor fraction of adult hemoglobin (HbA_2), has become functionally insignificant by virtue of its very low level in the erythrocyte. It is likely that the δ-globin gene is a "pseudogene in evolution." HbA_2 is clinically useful, however, for characterizing hemoglobinopathies such as β-thalassemia. In time, its expression may be totally abolished as it acquires an inactivating mutation. The pseudogenes dispersed within both globin gene clusters provide interesting glimpses into the evolutionary history of globin genes. Pseudogenes are inactive remnants of previously expressed genes. As a result of relaxed selection, their mutation rates are higher than those of surrounding active genes.

The expression of the human globin genes is highly regulated. Globin is synthesized in only one tissue—erythroid cells—and only during a narrowly defined stage of erythroid progenitor cell differentiation—the 5 to 7 days that commence with the proerythroblast stage and end when the enucleated reticulocyte loses the last traces of its RNA. Within the confines of these strict tissue-specific and differentiation stage-specific boundaries, the globin genes are extraordinarily active. By the late normoblast and reticulocyte stages, 90% to 95% of all protein synthesis in these cells is globin synthesis.

Individual globin genes are expressed at different levels in developing erythroblasts of human embryos, fetuses, and "adults" (i.e., 37 to 38 weeks of gestation and beyond). Different subsets of α- and non–α-genes are expressed and silenced at each developmental stage. Moreover, the overall balance of non–α-globin, α-globin, and heme production is maintained throughout each of these complex switching events. The complex mechanisms ensuring the proper tissue-specific, differentiation stage-–specific, and ontologic stage–specific expression are incompletely defined. Much information about relevant DNA control elements and transcription factors is emerging. These topics are discussed after a review of the ontogeny of hemoglobin.

Ontogeny of Hemoglobin

The hemoglobin composition of the erythrocyte depends on when in gestation or postnatal development it is measured. This is a result of sequential activation and inactivation (i.e., switching) among genes within the α- and non–α-globin gene clusters (see Fig. 31-8). What controls these switches in globin gene transcription is not understood. The two early embryonic hemoglobins consist of ζ- and ε-globin chains (Hb Gower-1) and α- and ε-globin chains (Hb

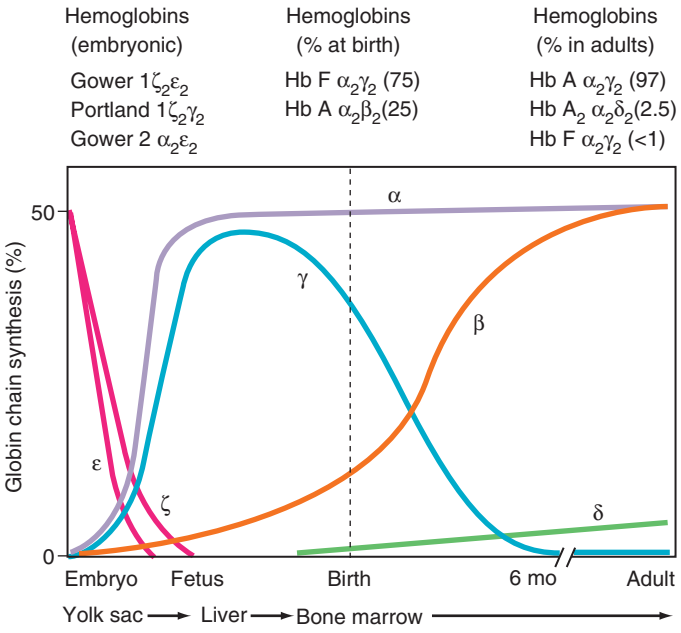

Figure 31-8 HEMOGLOBIN (Hb) SWITCHING DURING EMBRYONIC, FETAL, AND ADULT DEVELOPMENT. The ζ and ε genes are transcribed during embryonic development and are soon replaced by the fetal γ- and adult α-globin gene. At birth, fetal hemoglobin (HbF) forms approximately 75%, and hemoglobin A forms 25% of the total. Transcription of the γ gene begins to decrease before birth, and by 6 months of age, this gene is expressed only at very low levels. Expression of the δ-globin gene begins near birth. In adults, hemoglobin A makes up approximately 97%, hemoglobin A_2 approximately 2.5%, and HbF less than 1% of the total. *(From Steinberg MH: Hemoglobinopathies and thalassemias. In Stein JH, editors:* Internal medicine, *ed 4, St. Louis, 1994, Mosby-Year Book, p 852.)*

Gower-2). The ζ-globin gene is akin to the α-globin genes but is expressed only during early embryogenesis. The ε-embryonic globin chain is a β-like element. The combination of ζ- and γ-globin chains forms hemoglobin Portland. These early hemoglobins are made primarily in yolk-sac erythroblasts and are detectable only during the very earliest stages of embryogenesis except in certain pathologic states, in which they may persist until gestation is complete. The major hemoglobin of intrauterine life is HbF, which consists of two α- and two γ-globin chains. Expression of the γ-globin gene begins early in embryogenesis, peaks during midgestation, and begins a rapid decline just before birth. By 6 months of age in normal infants, only a remnant of prior γ-globin gene expression remains. The level of HbF in the blood declines rapidly thereafter to less than 1% of the total. Expression of the α-globin gene starts early in the first trimester, peaks quickly, and is sustained for life. Expression of the β-globin gene also commences early in gestation and reaches its zenith within a few months after birth. The combination of α-globin with β-globin chains forms hemoglobin A (HbA), the predominant hemoglobin of postnatal life. Adult cells also contain HbA2. The δ-globin gene, which directs synthesis of the non–α-globin chain of HbA2, is very inefficiently expressed. Only low levels of HbA2 are present; defects in the δ-globin gene are of no clinical consequence. In adult blood, HbF is not evenly distributed among erythrocytes and is present in only a very small number of RBCs, called F cells. HbA2 is present in all RBCs, albeit at levels less than 3.5% of the total hemoglobin in adult life.

Hemoglobin Biosynthesis and Its Regulation

Throughout development, genes coding for α-globin, non–α-globin, and heme exhibit coordinated expression. Almost equal amounts of each of the moieties that ultimately constitute the hemoglobin tetramer are made. Excess unpaired globin chains and mutant globins are removed from the cell by ATP-dependent proteases, ensuring a balance between accumulation of α- and non–α-globin chains. Balanced chain synthesis and coordination of globin chain production with synthesis of heme are important because hemoglobin tetramers are highly soluble, but the components of hemoglobin (i.e., unpaired chains, protoporphyrin, and iron) are not. Precipitation of any of these is deleterious to cell survival. Erythroblast proteases are not efficient enough to eliminate the substantial excesses of unpaired chains that accumulate when an α- or non–α-gene is selectively impaired by severe thalassemia mutations. The mechanisms regulating heme production and some of the interactions between heme and globin synthesis are discussed in Chapter 36.

The proper production of the individual globin chains within erythroid tissues at the appropriate states of differentiation and development is predominantly ensured by regulation at the level of transcription. The onset of phenotypic maturation at the proerythroblast stage is marked by the onset of globin mRNA biosynthesis in dramatically increasing quantities. Expression of α- and non–α-globin genes begins at essentially the same time, although some studies suggest a slightly earlier onset for α-globin gene expression. Transcription persists at a high level throughout most of the remainder of erythropoiesis, declines as the nucleus condenses, and is eventually lost in late erythroblasts. Even as the absolute rates of globin gene transcription begin to decrease, however, the relative percentage of total transcriptional activity devoted to globin gene expression continues to increase; this reflects the silencing of transcription of almost every other gene in the erythroblast.

The transcriptional activation of the globin genes is the major event that must be understood to define and manipulate the regulation of hemoglobin biosynthesis and hemoglobin switching. However, posttranscriptional mechanisms contribute to the final distribution of globin and nonglobin mRNAs and to the balance of α- and non–α-globins within the erythroblasts. When compared with many other mRNAs, such as cytokine mRNAs, globin mRNAs are extraordinarily stable. Their half-lives have been estimated at 30 to 50 hours. Most other mRNAs have turnover rates, or half-lives, measured within the range of a few minutes to 5 or 6 hours. The increase in the percentage of total mRNA that is globin mRNA is greatly accentuated because the newly transcribed globin mRNAs accumulate and remain quite stable in the cell, but nonglobin mRNAs, which are no longer being produced, are also disappearing at a faster rate. Consequently, the mRNA content of the reticulocytes consists of 90% to 95% globin mRNA.

The transcription rates of the α- and non–α-globin genes are not precisely equal. (This phenomenon has been studied in detail only in adult erythroid cells expressing the α- and β-globin genes.) A slight, but reproducibly detectable, excess of α-globin mRNA is present in erythroblasts. However, β-globin mRNA is translated somewhat more efficiently than α-globin mRNA. These counterbalancing forces result in almost equal syntheses of α- and β-globin polypeptide chains. There is a very slight excess of α-globin production, resulting in a small pool of free α-globin chains.

Alpha hemoglobin-stabilizing protein (AHSP), a small protein present at high concentrations in RBCs, binds specifically to the α-globin polypeptide, protecting the unstable free α-globin chain by inhibiting heme loss and oxidant-mediated chain precipitation. It remains unclear whether mutations of this protein can modify the phenotype of β-thalassemia by increasing the imbalance in globin chain synthesis. Some α-globin chain variants, because the mutations alter AHSP binding, are associated with mild thalassemia-like features.

Newly synthesized β-globin chains are rapidly and completely incorporated into αβ dimers that spontaneously associate as tetramers. Hemoglobin tetramers are remarkably stable throughout the lifespan of the circulating RBC by virtue of their long half-lives. Only small amounts sustain oxidative or proteolytic damage.

Hemoglobin molecules are exposed for prolonged periods to chemically active compounds in the milieu of the bloodstream. They

often become nonenzymatically modified by such processes as glycosylation, acetylation, and sulfation. Glycosylation occurs more extensively during periods of hyperglycemia and leads to elevated levels of the glycosylated form of HbA, HbA_{1c}. This phenomenon is the basis of a useful test for control of the blood sugar in diabetes. Other posttranslational modifications are of little clinical importance except as already noted for 2,3-BPG, carbon dioxide (CO_2), and NO.

Transcriptional Regulation of Globin Gene Expression

Precise regulation of the globin gene clusters involves a complex interplay between trans-acting proteins, such as transcription factors, and cis-acting sequences that act as promoters, enhancers, and silencers of gene activity. DNA-binding proteins interact with sequences in regulatory regions of the globin gene cluster and with other proteins through specific protein–protein interactions, forming DNA-–protein complexes that regulate gene transcription. Trans-acting factors mediate the remodeling of chromatin structure, influencing gene expression for the entire globin gene clusters. Mutations in the cis-acting sequences or trans-acting proteins cause dysregulated expression of globin genes, resulting in thalassemia-like syndromes. Elucidating the full extent of sequences required for appropriate expression of globin genes will inform the development of constructs for gene therapy.

The nuclei of erythroid cells contain numerous proteins that have been identified as transcription factors, including GATA1, NFE2, and EKLF. GATA1 is named on the basis of the DNA sequence motif (T/A) GATA (A/G), the GATA motif that it recognizes and binds. It is a zinc finger class DNA-binding protein (see Chapter 24). Activity of GATA1 requires binding to a zinc finger protein cofactor called FOG1 (named for Friend of GATA1). NFE2 recognizes the DNA sequence motif (T/C) GCT GA (C/G) TCA (T/C). It is a member of the B-zip class of transcriptional activators. GATA1 and NFE2 were originally identified and cloned on the basis of their interactions with their cognate sequences in the globin genes. Erythroid Kruppel-like factor (EKLF, also called KLF1) may be the most specific of the erythroid transcription factors yet discovered. EKLF interacts specifically with the β-globin gene promoter and may influence the γ-β switch. Mice homozygous for disruption of the EKLF gene have lethal β-thalassemia. Alone, GATA1, NFE2, EKLF, and FOG1 cannot be the sole determination of tissue specificity of the globin genes. Together, they form a robust transcriptional network that regulates erythroid genes, including the globin genes. Mutations in GATA1 or FOG1 can cause β-thalassemia and thrombocytopenia in patients.

The regions of the globin gene clusters with essential regulatory sequences and erythroid-specific chromatin remodeling extend far beyond the coding sequences of the globin genes. The key regulatory element for the α-globin gene (HS –40) lies in an erythroid-specific DNase I hypersensitive site 40 kb from the α-globin gene. The LCR is critical for high level expression of the β-globin gene cluster, consisting of five sites that are hypersensitive to DNase I (HS 1-5) (see Chapter 1). Patients with deletion of the HS –40 site exhibit α-thalassemia, and patients with deletions of the β-globin LCR develop β-thalassemia; however, the thalassemia can be a result of changes in chromatin caused by the large deletion. Similarly, transgenic mice bearing deletions of these critical regulatory regions have severely restricted expressions of the respective globin genes.

The LCRs contain binding sites for the major erythroid transcription factors, including GATA1, EKLF, and NFE2, as well as sites for transcription factors found more widely distributed in many cell types. The LCRs loop to interact directly with the promoters of individual globin genes, resulting in a complex termed the *active chromatin hub*. The resulting structure enables high level expression of globin genes in erythroid cells at the appropriate developmental stages. Additional elements act as insulators, protecting expressed genes from gene silencing through the regulation of chromatin structure.

BCL11a is a transcriptional repressor that decreases fetal hemoglobin expression in adult tissues. Polymorphisms in the BCL11a gene are powerfully associated with HbF levels, including in patients with sickle cell disease. Inhibition of BCL11a increases HbF levels and attenuates the phenotype of sickle cell disease in a murine model and is therefore an attractive therapeutic strategy for the treatment of sickle cell disease.

Transcription factors recruit enzymes that remodel chromatin structure. "Open" chromatin, or euchromatin, generally appears cytogenetically uncondensed and is associated with hyperacetylated histones, unmethylated CpG dinucleotides, and active transcription. ATRX is a protein that has been implicated in the modulation of chromatin structure at the α-globin locus. Mutations in the *ATRX* gene, located on the X chromosome, cause a syndrome of α-thalassemia, severe mental retardation, facial dysmorphism, and urogenital abnormalities. ATRX, a member of the SNF2 family of helicase/ATPases, localizes to pericentromeric heterochromatin during interphase and mitosis and contains a plant homeodomain (PHD)-like domain that is found in chromatin-associated proteins. Cells with a mutated *ATRX* gene have altered patterns of DNA methylation. The ATRX protein therefore exemplifies the connections among DNA methylation, chromatin remodeling, and expression of the α-globin genes.

Chromatin structure can be manipulated pharmacologically through the influence of drugs on methylation and histone acetylation. Cytidine analogs such as 5-azacytidine and its less toxic derivative, decitabine, inactivate DNA methyltransferases, inducing γ-globin gene expression and increasing HbF levels in patients with sickle cell anemia. Histone deacetylase inhibitors are being studied as agents to increase γ-globin expression.

Posttranscriptional, Translational, and Posttranslational Mechanisms

Processed globin mRNA is exported from the nucleus to the cytoplasm by a mechanism that is not clearly defined. mRNA translation occurs in the cytoplasm (see Fig. 31-7). The triplet codons or mRNA are recognized by the anticodons of specific tRNAs that bring activated amino acid residues to the nascent polypeptide chains. The process of translation, in which an mRNA template directs the synthesis of protein, is typically divided into three phases: initiation, elongation, and termination (see Chapter 1). Each phase is regulated by a variety of protein factors.

The globin mRNA molecule becomes associated with four to six ribosomes, forming the polyribosome. At least 11 eukaryotic translation initiation factors interact with the polyribosome. They mediate stabilization of a preinitiation complex, binding of the initiator methionine tRNA to ribosomal subunits, binding of mRNA to the preinitiation complex, stabilization of mRNA binding, recognition of the cap site at the 5′ end of mRNA, and release of initiation factors from the preinitiation complex. Several elongation and termination factors have also been defined. Initiation or an early step in the elongation process is the rate-limiting factor.

The first posttranslational step in tetramer formation is the combination of α- and non–α-globin chains to form dimers, an event that appears to depend on the relative charge of each globin subunit. The dimers then form tetrameric hemoglobin. Because of charge differences among non–α-globin chains, there is a hierarchy or affinity of these chains for α-globin chains. The combination of α- and β-globin chains is most favored followed by a combination of α-, γ-, and δ-globin chains. Certain mutant hemoglobins that have gained or lost a charge may alter this hierarchic arrangement. This may influence the proportion of variant hemoglobin present, especially when the patient also inherits an α-thalassemia syndrome, in which the synthesis of α-globin chains is reduced. The supply of available α-globin chains is then limited, and non–α-globin chains compete with one another to form tetramers with the limiting α-globin chain pool.

Globin chain biosynthesis and heme synthesis are mutually important. Heme plays a role in the regulation of the initiation complex. A deficiency of heme (e.g., in iron deficiency) is associated with the accumulation of a repressor of translation initiation factors. Translation of β-globin mRNA appears to be initiated more efficiently than α-globin mRNA, conferring on the associated anemia some of the features of mild α-thalassemia. This phenomenon occurs because heme deficiency depresses the availability of initiating factors for which the less efficient α-mRNA must compete with the more efficient β-mRNA.

The identification of genetic mutations that cause congenital and acquired forms of anemia provide further insight into the pathways required for the coordinated production of globin and heme. More than half of patients with Diamond-Blackfan anemia, a disorder characterized by a severe macrocytic anemia and a paucity of erythroid progenitor cells, have heterozygous germline mutations in the *RPS19* gene or other genes encoding ribosomal proteins. Similarly, the macrocytic anemia in patients with myelodysplastic syndrome and a deletion of chromosome 5q is caused by heterozygous deletion of another ribosomal protein gene, *RPS14*. Haploinsufficiency for these ribosomal protein genes activates the p53 pathway, leading to cell cycle arrest and apoptosis selectively in the erythroid progenitor cells.

Table 31-1 Classification of Hemoglobinopathies and Thalassemias

Structural hemoglobinopathies—mutations altering the amino acid sequence of a globin chain and altering physical or chemical properties of the hemoglobin tetramer in such a way that function is deranged
Abnormal Hemoglobin (Hb) Polymerization—Sickle Cell Hemoglobin (HbS); Hemolysis, Vasoocclusion
Abnormal hemoglobin crystallization (e.g., HbC)
High oxygen affinity—polycythemia (Hb Zurich)
Low oxygen affinity—cyanosis (Hb Kansas)
Hemoglobins that oxidize or precipitate too readily—unstable hemoglobins (Hb Köln)
M hemoglobins—methemoglobinemia, cyanosis (e.g., Hb Milwaukee)
Thalassemia—Defective Production of Globin Chains With Hypochromia, Anemia, Hemolysis, Altered Erythropoiesis
α-Thalassemia
β-Thalassemia
δβ-Thalassemias, γδβ-thalassemias, αβ-thalassemias
"Thalassemic" Hemoglobinopathies and Dominantly Inherited Thalassemias—Mutations Altering the Synthesis and Structure or Function of the Hemoglobin Gene Products (e.g., HbE, Hb Terre Haute, Hb Lepore, Hb Constant Spring)
Hereditary persistence of fetal hemoglobin—persistence of high levels of fetal hemoglobin (HbF) into adult life
Pancellular—high HbF levels in all RBCs
Nondeletion forms
Deletion forms
Hb Kenya
Heterocellular—inherited increases in the percentage of F cells
Acquired hemoglobinopathies
Methemoglobinemia Caused by Toxic Exposures
Sulfhemoglobinemia caused by toxic exposures
Carboxyhemoglobinemia caused by toxic exposures
HbH in erythroleukemias
Acquired elevations in F cells and HbF
Erythroid stress (e.g., recovery from BM suppression)
BM dysplasias
Exposure to agents altering stem cells or gene expression (e.g., hydroxyurea, butyric acid)

BM, Bone marrow; *Hb,* hemoglobin; *RBC,* red blood cell.

Refractory anemia with ring sideroblasts (RARS) is a subtype of myelodysplastic syndrome characterized by iron-loaded mitochondria evident on Prussian blue staining. In the majority of RARS cases, somatic mutations are present in the *SF3B1* gene, encoding a core member of the RNA splicing machinery. The precise targets of SF3B1 have not been identified.

NOSOLOGY OF HEMOGLOBINOPATHIES

Inherited abnormalities of the hemoglobin molecules that cause morbidity are called hemoglobinopathies and thalassemias. Many of these conditions produce diseases (e.g., sickle cell anemia, thalassemia, unstable hemoglobins, M hemoglobins) that are especially important to hematologists. A few acquired conditions lead to modifications of hemoglobin (e.g., carbon monoxide exposure, producing carboxyhemoglobinemia, nitrite exposure causing methemoglobinemia) that produce clinical abnormalities. These situations are summarized by the term acquired hemoglobinopathies or dyshemoglobinemias.

Most of the more than 1200 mutations of the globin gene that have been described produce no disease or only trivial clinical effects. The remainder can be classified according to the hematologic and clinical phenotypes that cause reduced solubility with hemolytic anemia (unstable hemoglobins and polymerizing hemoglobins, such as sickle hemoglobin); hemoglobins with altered oxygen affinity; hemoglobins predisposing to methemoglobin formation; and the thalassemias involving abnormal synthesis of one or more globin chains with anemia, hemolysis, and alterations of erythropoiesis. Some mutations, such as that responsible for HbE, can alter the structure and synthesis of the molecule. A classification of hemoglobinopathies and thalassemias is provided in Table 31-1. Individual conditions are discussed in the chapters already cross-referenced in earlier sections of this chapter.

CHAPTER 32

APPROACH TO ANEMIA IN THE ADULT AND CHILD

Peter W. Marks

Anemia is one of the most commonly encountered problems in hematology. Although a few entities are responsible for the majority of cases, there are numerous less common causes of anemia in adults and children. A systematic diagnostic approach to the evaluation of anemia, extracting the maximum amount of information available from the complete blood count, reticulocyte count, and peripheral blood smear, can often rapidly point to the appropriate diagnosis and reduce or eliminate the need for additional diagnostic testing.

OVERVIEW OF ERYTHROPOIESIS

Accurate diagnosis of anemia is facilitated by an understanding of red blood cell (RBC) production. Erythropoiesis is the regulated process leading to the production of mature erythrocytes. Stem cells in the bone marrow (BM) are stimulated by the hormone erythropoietin and other factors to proliferate and differentiate along a pathway of recognizable precursors that ultimately leads to extrusion of the nucleus from cells containing a high concentration of hemoglobin and some residual RNA (Fig. 32-1).[1] These cells that are identified as reticulocytes by staining of the residual RNA become mature erythrocytes as the RNA is degraded, which under normal conditions happens in a day. The RBCs then circulate for 100 to 120 days before being removed from the circulation by macrophages in the spleen and other cells of the reticuloendothelial system.[2] At steady state under physiologic conditions, the production and destruction of erythrocytes is equivalent. This process is driven in large part by the hormone erythropoietin, which is produced in a regulated fashion by periglomerular cells in the kidney (≈90%) and constitutively by the liver (≈10%).[3] Because preservation of oxygen delivery to tissues is so important, the oxygen-sensing regulatory proteins located in the kidney respond to decreased oxygen tension from any cause such as blood loss, high altitude, or cardiac shunts with the production of erythropoietin (Fig. 32-2). This hormone then travels through the bloodstream and stimulates RBC production in the BM. Provided that there are adequate nutrients, including folate, vitamin B_{12}, and iron, the precursors in the BM proliferate and mature and are released into the circulation, ultimately expanding the pool of erythrocytes.[4] The increase in oxygen delivery to the kidney then reduces the stimulus for erythropoietin production.

DEFINITION OF ANEMIA

Anemia is defined as a reduction in the RBC mass. Because of a variety of factors, the RBC mass normally changes during the lifespan of an individual and may be different in males and females.[5] Understanding the changes that occur is critical to appropriately identifying what constitutes anemia (Table 32-1). The relatively elevated level of hemoglobin present at birth declines over the first 1 to 2 months of life to levels that are lower than those seen in adulthood. In later childhood, the hemoglobin values are similar and increase modestly over time. Around puberty, girls have reached adult levels of hemoglobin, and androgenic steroids lead to a continued increase in hemoglobin in boys through about age 18 years. This approximately 1.5 g/dL difference between males and females persists through much of adult life until about age 70 years, when the hemoglobin value in men begins to decline. Over the next 2 decades, the hemoglobin value declines by about 1 g/dL in men while decreasing by only approximately 0.2 g/dL in women.[6] Thus, at age 90 years, there is only a modest difference between the mean hemoglobin values observed in men and women (14.1 vs. 13.8 g/dL).

MECHANISMS OF ANEMIA

Although a complete review of all of the mechanisms leading to anemia is beyond the scope of this chapter, an appreciation of some of the mechanisms is useful before approaching the diagnosis of anemia in adults and children. Three broad categories of anemia are blood loss anemia, hypoproliferative anemia, and hemolytic anemia. Blood loss may occur acutely or chronically. When blood is lost acutely through hemorrhage, it may take several hours before a decline in hemoglobin concentration is observed because of the time required for restoration of the plasma volume and equilibration. Several days may elapse before an appropriate reticulocytosis is noted. Chronic blood loss ultimately leads to hypoproliferative anemia because of iron deficiency.

Hypoproliferative Anemia

When used broadly, the term *hypoproliferative anemia* refers to entities that manifest as an inability to produce an adequate number of erythrocytes in response to appropriate signals. Although there are many different causes, the hallmark of hypoproliferative anemia is a low reticulocyte count (Table 32-2). The etiology underlying this class of disorders may relate to the hypoproliferation of precursors within the BM, such as may be seen when there is BM replacement (myelophthisis), or to abnormal maturation of precursors in the BM, such as that which occurs in megaloblastic anemia (folate deficiency, vitamin B_{12} deficiency, myelodysplastic syndromes [MDS], and others). In the latter case of megaloblastic anemia, the BM often is packed. However, intramedullary demise of precursors prevents the formation and release of mature RBCs.

By far, the most common cause of hypoproliferative anemia globally is iron deficiency.[7] It is estimated that about 2% of infants and children may become iron deficient purely because of inadequate dietary intake and that 4% of women ages 20 to 49 years of age in the United States have iron-deficiency anemia primarily because of inadequate dietary intake in the setting of menstruation and childbirth. Iron deficiency is also commonly encountered in older individuals as well (≈2% of individuals older than age 50 years), and it should provoke a thorough search for its etiology, which in both men and nonmenstruating women frequently is gastrointestinal blood loss. After iron deficiency, acute or chronic inflammation and renal disease are common etiologies of anemia.[8,9] BM failure states and BM replacement caused by hematologic malignancies or solid tumors are less common causes of anemia and are often accompanied by other hematologic manifestations, such as leukopenia and thrombocytopenia.

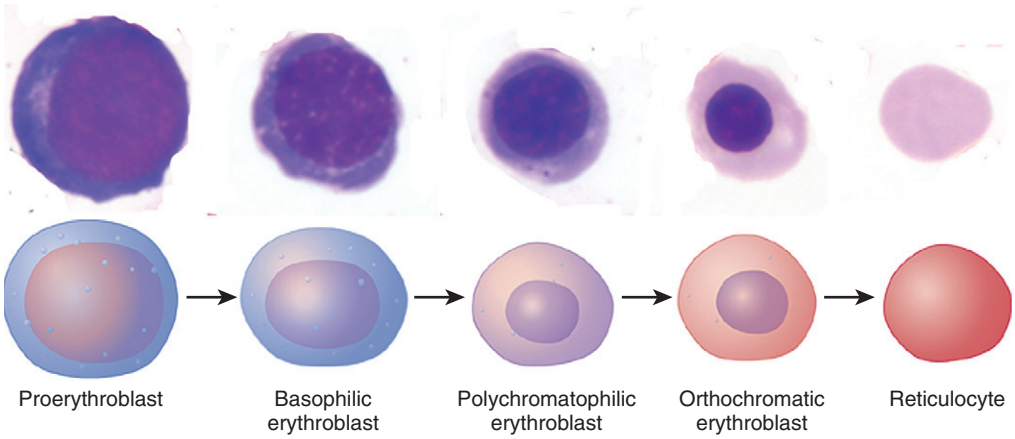

Figure 32-1 OVERVIEW OF ERYTHROPOIESIS.

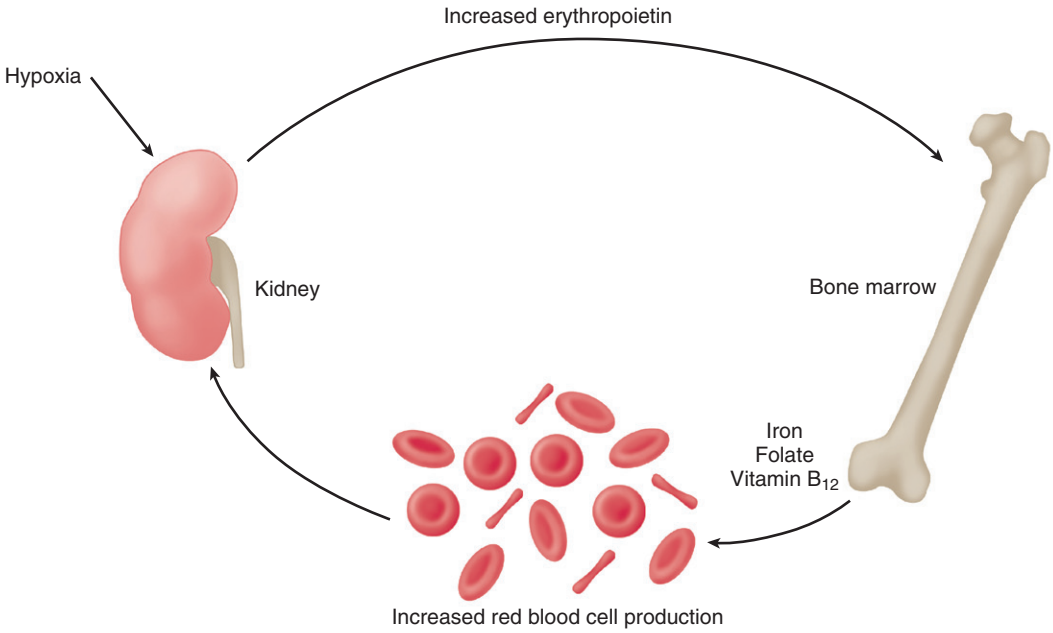

Figure 32-2 REGULATION OF ERYTHROPOIESIS.

Hemolytic Anemia

The causes of hemolytic anemia are quite varied and may be congenital or acquired.[10] The hallmark of hemolytic anemia is an elevated reticulocyte count (see Table 32-2). Other features commonly associated with hemolytic anemia include an elevated lactate dehydrogenase (LDH) level, increased unconjugated (indirect) bilirubin level, and decreased haptoglobin level. Hemolytic anemia also may manifest with distinctive changes on the peripheral blood smear. Congenital causes include the hemoglobinopathies, enzymopathies (predominantly glucose-6-phosphate dehydrogenase [G6PD] deficiency), and membrane disorders.[11] Acquired conditions include autoimmune hemolytic anemia, microangiopathic hemolytic anemia, hemolysis related to infections, and acquired membrane disorders such as those caused by liver disease (spur cell of anemia) and paroxysmal nocturnal hemoglobinuria.[12]

COMPARISON OF ETIOLOGIES OF ANEMIA IN ADULTS AND CHILDREN

As already noted, the designation that anemia is present relies on comparison of the patient's hemoglobin or hematocrit with an age- and sex-appropriate normal range (see Table 32-1). Although many types of anemia may occur across the age spectrum, certain types tend to be identified more commonly in either adults or children, and some are primarily identified in neonates. In children, the most common causes of anemia are related to nutritional deficiency or to a primary hematologic process, either hereditary or acquired. In contrast, in adults, the most common causes of anemia are iron deficiency caused by blood loss or anemia caused by systemic illness or malignancy (Table 32-3).

Anemia in Children

Hypoproliferative anemia in children may be associated with either acquired or congenital etiologies. Acquired cases are most commonly caused by nutritional deficiency but also include those caused by acquired aplastic anemia, transient erythroblastopenia of childhood, the anemia of acute inflammation, and marrow replacement caused by malignancy.[13] Congenital causes include Diamond-Blackfan anemia and other rare syndromes, including refractory sideroblastic anemia and the congenital dyserythropoietic anemias.[14] Iron deficiency may occur in children because of a diet that is rich in cow's milk to the exclusion of other iron-containing foods. This is

MCH, Mean corpuscular hemoglobin; *MCHC,* mean corpuscular hemoglobin concentration; *MCV,* mean corpuscular volume.

particularly common during the first 2 years of life. The anemia may be quite severe and may be associated with a mean corpuscular volume (MCV) of 50 to 65 fL. Acquired aplastic anemia, as opposed to pure RBC aplasia, is associated with bicytopenia or pancytopenia. Transient erythroblastopenia of childhood is an acquired disorder that generally occurs during the first 3 years of life in otherwise healthy children, although it can be seen in children from 6 months to 10 years old. It is thought to have a viral or immunologic cause and resolves without specific intervention. The anemia of acute inflammation may be encountered in children who are hospitalized and is generally transient, resolving when the underlying condition has improved. Leukemia may result in BM replacement and is usually associated with abnormalities in other cell lineages in addition to RBCs.

Hemolytic anemia in children is most commonly associated with inherited disorders of hemoglobin or the RBC membrane.[15] However, acquired causes such as autoimmune hemolytic anemia and microangiopathic hemolytic anemia, particularly *Shiga* toxin–associated hemolytic uremic syndrome (HUS), also occur.[16] In older children, many etiologies of hemolytic anemia overlap with those considered in adults, and a similar diagnostic algorithm may be appropriate. However, in newborns, inherited causes of hemolytic anemia must be distinguished from more pronounced cases of the physiologic hyperbilirubinemia that occurs. After true hemolysis has been identified in an infant, the differential diagnosis is relatively limited (Fig. 32-3). Immune-mediated hemolysis may result from ABO, Rh, or minor blood group incompatibility.[17] Other causes include metabolic disorders and disorders of the RBC membrane. Of note, however, is the fact that hemoglobinopathies, such as sickle cell disease and β-thalassemia, are silent during the newborn period and only become manifest at 4 to 6 months of age when the fetal-to-adult hemoglobin transition has been completed. Newborn screening programs in the United States may provide salient information in this regard on the presence or absence of a hemoglobinopathy. Alternatively, ethnic background and family history may be helpful in arriving at the appropriate diagnosis.

Anemia in Adults

Hypoproliferative anemia in adults is relatively common. If acute blood loss is excluded, hypoproliferative causes are the most common entities associated with anemia in adults. These are iron deficiency, inflammation (anemia of chronic disease), and renal disease (Fig. 32-4). The megaloblastic anemias that represent maturation abnormalities, including folate and vitamin B_{12} deficiency, are often categorized along with the hypoproliferative anemias because they present with a low reticulocyte count as well. Drugs and toxins such as ethanol can also be associated with hypoproliferative anemia. Pure RBC aplasia may be associated with other diseases (thymoma) or viral infection (parvovirus B19) or be idiopathic.[18] Finally, MDS may present with hypoproliferative anemia, as may an infiltrative process such as myelofibrosis or acute leukemia. The distinction between the various causes of anemia is facilitated by historical factors, physical findings, and concomitant laboratory abnormalities in conjunction with review of the MCV and RBC distribution width (RDW) along with the peripheral blood smear. In the setting of a low reticulocyte count, MCV values below 70 fL are most commonly associated with iron-deficiency anemia, and those above 120 fL are most commonly associated with folate or vitamin B_{12} deficiency. The differential diagnosis broadens for MCV values that fall just outside of the normal range. For example, in the setting of a low reticulocyte count, MCV values in the range from 75 to 80 fL may be associated with iron-deficiency anemia, the anemia of inflammation, and endocrine causes of anemia. MCV values between 100 and 110 fL may be associated with folate or vitamin B_{12} deficiency, aplastic anemia, MDS, liver disease, and immune hemolytic anemias.

Hemolytic anemia in adults is less common than hypoproliferative anemia, and the differential diagnosis is broad. Congenital causes associated with mild to moderate hemolysis may be clinically silent until detected later in life.[19] This is particularly the case for milder cases of β-thalassemia intermedia, sickle cell-SC disease and sickle-β^+-thalassemia, and hereditary spherocytosis. Additionally, the most common RBC enzymopathy (which is also the one of the most

Table 32-3 Comparison of the More Common Causes of Anemia in Children and Adult

Type of Anemia	Children	Adults
Hypoproliferative	• Nutritional deficiency (most commonly iron deficiency) • Acute inflammation • Transient erythroblastopenia of childhood • Acquired aplastic anemia • Marrow replacement caused by malignancy	• Iron deficiency • Anemia of inflammation (anemia of chronic disease) • Anemia of renal disease • Folate or vitamin B_{12} deficiency • Drugs or toxins • Pure RBC aplasia (viral or idiopathic) • MDS
Hemolytic	• Inherited hemoglobinopathies • Inherited membrane disorders • Autoimmune hemolytic anemia • Microangiopathic hemolytic anemia	• Inherited hemoglobinopathies with milder manifestations • Inherited membrane disorders with milder manifestations • G6PD deficiency • Autoimmune hemolytic anemia • Microangiopathic hemolytic anemia (DIC, TTP, HUS)

DIC, Disseminated intravascular coagulation; *G6PD,* glucose-6-phosphate dehydrogenase; *HUS,* hemolytic uremic syndrome; *MDS,* myelodysplastic syndrome; *RBC,* red blood cell; *TTP,* thrombotic thrombocytopenic purpura.

common human enzyme defect deficiencies), G6PD deficiency, does not present until individuals encounter oxidant stress either because of infection or drugs such as sulfonamides and antimalarials.[20] Acquired hemolytic anemias include autoimmune hemolytic anemia, which is often associated with hematologic malignancies or rheumatologic disorders, and the microangiopathic hemolytic anemias, including disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura (TTP), and HUS.[21] Distinction of the various causes of hemolytic anemia is also facilitated by the associated historical features, physical findings, and laboratory abnormalities of the clinical presentation. For these disorders, review of the peripheral blood smear may be particularly revealing as to the etiology.

SYSTEMATIC APPROACH TO ANEMIA

The correct diagnosis of anemia can often be determined by combining a thorough history and physical examination with review of the complete blood count, concentrating particularly on the MCV and RDW, along with review of the reticulocyte count and the peripheral blood smear.

History and Physical Examination

Because anemia can be a primary disorder or secondary to other systemic processes, a careful history and physical examination provide valuable insight into the potential cause. Fatigue often accompanies anemia, but it is very nonspecific and may be related to systemic illness. Nonetheless, determining the concomitant presence of a systemic inflammatory disorder, infection, or malignancy that may be associated with fatigue can be critical in determining the underlying causes of anemia in both adults and children. The medical history may also be quite informative. For example, a history of diabetes mellitus can be associated with significantly impaired renal production of erythropoietin even in the setting of only a mildly elevated creatinine level. Because certain medications may be associated with BM depression or, alternatively, the development of autoimmune hemolytic anemia, all pharmacologic agents, prescribed and over the counter, including alternative medicines, should be reviewed. Occupational history is occasionally relevant, as in the case of individuals, such as welders, who might have been exposed to lead or other potentially BM toxic agents. Social history can be important. A history of intravenous drug use might suggest the possibility of virally transmitted diseases, such as HIV, which may be associated with anemia. Dietary history is also very important, particularly in young and elderly individuals with anemia. The finding of pica in adults (most commonly ice chips or cornstarch) is well known to be associated with iron-deficiency anemia.[22] Ingestion of paint chips may suggest the need to investigate the possibility of toxic lead ingestion. A family history of anemia is highly relevant in the evaluation of children with anemia. However, it is also relevant in adults because certain congenital anemias, such as milder forms of $S\beta^+$-thalassemia and hereditary spherocytosis, occasionally first become clinically apparent in adulthood.

The significance of pallor on physical examination is in many ways similar to the historic feature of fatigue: it is a common but nonspecific finding. More specific findings may be found in certain types of anemia. For example, angular cheilitis (cracking at the edges of the lips) and koilonychia (spooning of the nails) may accompany iron-deficiency anemia. Splenomegaly may be present in patients with anemia arising from a wide variety of different causes. When

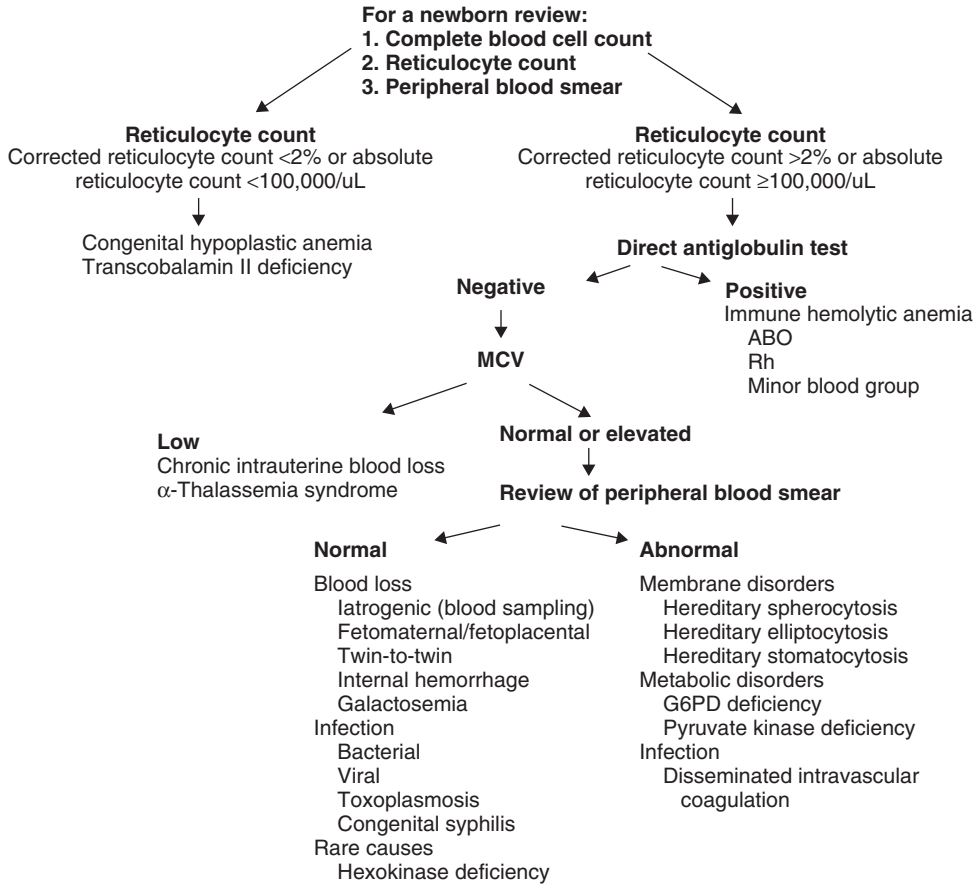

Figure 32-3 APPROACH TO THE DIFFERENTIAL DIAGNOSIS OF ANEMIA IN A NEWBORN. *G6PD,* Glucose-6-phosphate dehydrogenase; *MCV,* mean corpuscular volume.

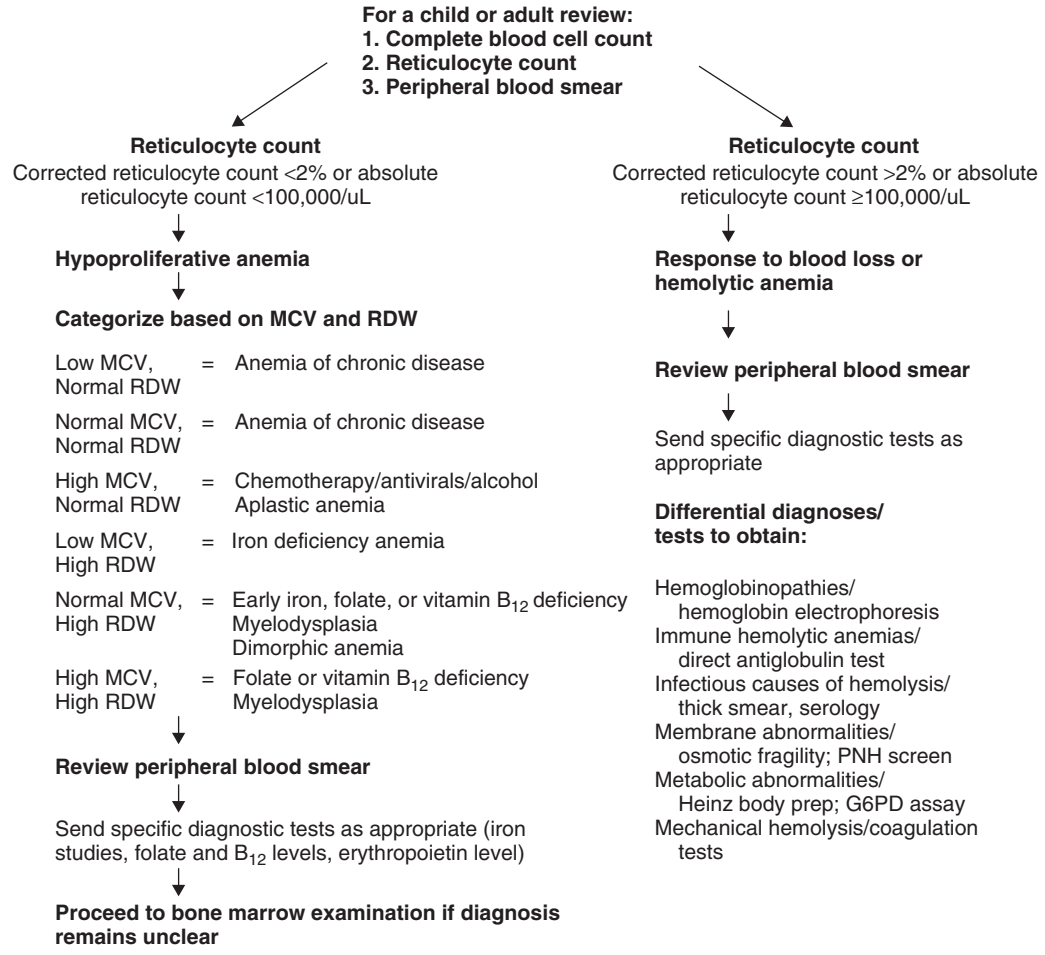

Figure 32-4 APPROACH TO THE DIFFERENTIAL DIAGNOSES OF ANEMIA IN ADULTS AND CHILDREN. *G6PD,* Glucose-6-phosphate dehydrogenase; *MCV,* mean corpuscular volume; *PNH,* paroxysmal nocturnal hemoglobinuria; *RDW,* red blood cell distribution width.

present early in life, it is suggestive of a congenital hemolytic anemia, such as thalassemia, sickle cell disease, or hereditary spherocytosis. When found for the first time later in life, splenomegaly may indicate an acquired disorder, such as autoimmune hemolytic anemia, lymphoproliferative disease, or a myeloproliferative disease such as myelofibrosis. Other physical findings can also sometimes provide insight relevant to the investigation of anemia when combined with historic features and laboratory data. Although anemia itself may lead to the presence of systolic cardiac murmurs, the finding of an increased cardiac murmur in an anemic patient with a prosthetic aortic valve and new microangiopathic change on peripheral smear may indicate that investigation into the possibility of perivalvular leak or prosthetic dysfunction is in order.[23] Finally, because neurologic manifestations can accompany or even predate the anemia associated with vitamin B_{12} deficiency, findings such as loss of vibration or position sense in the extremities may be relevant.[24]

Reticulocyte Count

As a marker of RBC production, the reticulocyte count provides essential information in directing the initial investigation of anemia. Modern flow cytometers accurately determine the reticulocyte count using fluorescent probes that bind to the residual ribonucleic acid present in newly released RBCs.[25] These measurements are useful, are accurate, and reflect the state of erythropoiesis. However, when significant numbers of nucleated RBCs or nuclear debris are present in the peripheral blood, this diagnostic accuracy declines, and manual counting methods are generally preferable.

When the reticulocyte count is reported as a percentage, it needs to be adjusted for the total number of RBCs present. This correction can be made by multiplying the reticulocyte count by the patient's hematocrit divided by an age- and sex-appropriate normal hematocrit. No such correction is necessary when the reticulocyte count is reported as an absolute number or when it is converted to an absolute number by multiplying the percentage by the RBC number (in RBC/μL).

In the absence of anemia, the normal absolute reticulocyte count is between 25,000 and 75,000/μL. In the presence of anemia, an absolute reticulocyte count of less than 75,000/μL is indicative of a hypoproliferative process, and an absolute reticulocyte count of greater than 100,000/μL is indicative of hemolysis or an appropriate erythropoietic response to blood loss (see Table 32-2). Reticulocyte counts between 75,000 and 100,000/μL require interpretation in the context of other available clinical data, including the severity of anemia present.

Mean Corpuscular Volume and Red Blood Cell Distribution Width from the Complete Blood Count

Automated cell counters provide a wealth of information regarding the size, shape, and hemoglobin content of RBCs. The two parameters most useful in classifying anemia are the MCV and the RDW. MCV is reported in femtoliters (fL) and reflects average cell size. RDW is often reported in percent and represents the standard deviation of RBC volume divided by the mean volume. It reflects the variation in cell size in the population of RBCs.[26] These two parameters are useful because relatively reproducible changes in the MCV and RDW are associated with certain types of anemia (Table 32-4). Particularly when combined with the reticulocyte count, the MCV and RDW can significantly narrow the differential diagnosis (Table 32-5).

Examination of the Peripheral Blood Smear

Despite the development and availability of more sophisticated diagnostic testing, review of a well-made peripheral blood smear remains one of the most informative and rewarding diagnostic procedures.[27] It offers the chance to confirm the findings of the automated complete blood cell count, which can be inaccurate in the presence of nucleated RBCs or rouleaux formation. Review of the blood smear also allows for evaluation of other cell lineages, which might suggest a primary BM or infiltrative disease. For example, the finding of hypersegmented neutrophils suggests a megaloblastic process, and this morphologic abnormality can be seen in the blood smear before there are significant changes in the hemoglobin or MCV (see box on Systematic Approach to the Diagnosis of Anemia). Also, only the blood smear reveals the unique morphologic changes occurring with several of the various hemolytic disorders.

Several commonly encountered findings can be seen in RBCs on the peripheral blood smear (Table 32-6 and Fig. 32-5). Whereas microcytic, hypochromic RBCs are suggestive of iron-deficiency anemia or thalassemia (see Fig. 32-5, *F*) macrocytic RBCs with ovalocytes (oval RBCs) are suggestive of megaloblastic anemias (see Fig. 32-5, *G*). Some findings reflect organ dysfunction, such as echinocytes (burr cells) in uremia (see Fig. 32-5, *R*) or acanthocytes (spur cells) in severe liver disease (see Fig. 32-5, *S*), although acanthocytes may also be seen in rare conditions such as abetalipoproteinemia. Target cells may be seen in cases of liver disease but may also be present in hemoglobinopathies, including sickle cell disease and thalassemia (see Fig. 32-5, *W*). The presence of schistocytes or RBC fragmentation often reflects systemic disease, such as DIC, TTP, or HUS (see Fig. 32-5, *P*). Finding spherocytes on a smear is suggestive of autoimmune hemolytic anemia or hereditary spherocytosis (see Fig. 32-5, *H*). Occasionally, the clue to the correct diagnosis of a systemic illness comes in the form of the observation of intraerythrocytic inclusions, such as malarial (see Fig. 32-5, *O*) or babesial forms, and examination of a thick blood smear may be useful for the diagnosis of these disorders when a low parasite burden is suspected.

Bone Marrow Examination

Bone marrow aspiration and biopsy permit evaluation of cellular morphology and BM architecture, respectively. Special stains, flow

Table 32-4 Usefulness of the Mean Corpuscular Value and Red Blood Cell Distribution Width in the Diagnosis of Anemia

	Low MCV (<80 fL)	Normal MCV (80–99 fL)	High MCV (≥100 fL)
Normal RDW	Anemia of chronic disease α- or β-Thalassemia trait Hemoglobin E trait	Acute blood loss Anemia of chronic disease Anemia of renal disease	Aplastic anemia Chronic liver disease Chemotherapy, antivirals, or alcohol
Elevated RDW	Iron deficiency Sickle cell–β-thalassemia	Early iron, folate, or vitamin B_{12} deficiency Dimorphic anemia (for example, iron + folate deficiency) Sickle cell anemia Sickle cell disease Chronic liver disease Myelodysplasia	Folate or vitamin B_{12} deficiency Immune hemolytic anemia Cytotoxic chemotherapy Chronic liver disease Myelodysplasia

MCV, Mean corpuscular value; *RDW,* red blood cell distribution width.

Table 32-5 Combining the Reticulocyte Count and Red Blood Cell Parameters for Diagnosis

MCV, RDW	Reticulocyte Count <100,000/μL	Reticulocyte Count ≥100,000/μL
Low, normal	Anemia of chronic disease	
Normal, normal	Anemia of chronic disease	
High, normal	Chemotherapy, antivirals, or alcohol Aplastic anemia	Chronic liver disease
Low, high	Iron-deficiency anemia	Sickle cell–β-thalassemia
Normal, high	Early iron, folate, vitamin B_{12} deficiency Myelodysplasia	Sickle cell anemia, sickle cell disease
High, high	Folate or vitamin B_{12} deficiency Myelodysplasia	Immune hemolytic anemia Chronic liver disease

MCV, Mean corpuscular volume; *RDW,* red blood cell distribution width.

Table 32-6 Features of the Peripheral Blood Smear

Red Blood Cell Morphology	Definition	Interpretation
Polychromasia	Large, bluish RBCs lacking normal central pallor on peripheral blood smear; bluish stain is the result of residual ribonucleic acid	Rapid production and release of RBCs from BM; elevated reticulocyte count; most commonly seen in hemolytic anemia
Basophilic stippling	Many small bluish dots in portion of erythrocytes; comes from staining of clustered polyribosomes in young circulating RBCs	Seen in a variety of erythropoietic disorders, including acquired and congenital hemolytic anemias and occasionally in lead poisoning (lead inhibits pyrimidine 5'-nucleotidase, which normally digests the residual RNA)
Pappenheimer bodies	Several grayish, irregularly shaped inclusions in a portion of erythrocytes visible on peripheral smear; composed of aggregates of ribosomes, ferritin, and mitochondria	Erythropoietic malfunction in congenital anemias such as hemoglobinopathies, particularly with splenic hypofunction or acquired anemias such as megaloblastic anemia
Heinz bodies	Several grayish, round inclusions visible after supravital staining with methyl crystal violet of the peripheral blood smear, often in the context of bite cells; represent aggregates of denatured hemoglobin	Indicative of oxidative injury to the erythrocyte, such as occurs in G6PD deficiency, or less commonly of unstable hemoglobins
Howell-Jolly bodies	Usually one or at most a few purplish inclusions in the erythrocyte visible on the routine peripheral blood smear; represent residual fragments of nuclei containing chromatin	Associated with states of splenic hypofunction or after splenectomy
Schistocytes	RBCs that are fragmented into a variety of shapes and sizes, including helmet-shaped cells; indicative of shearing of the erythrocyte within the circulation	Associated with microangiopathic hemolytic anemias, including DIC, TTP, or HUS, as well as other mechanical causes of hemolysis, such as prosthetic valves
Spherocytes	RBCs that have lost their central pallor and appear spherical; indicative of loss of cytoskeletal integrity from internal or external causes	Associated with hereditary spherocytosis, autoimmune hemolytic anemia; may also be observed in addition to schistocytes in the presence of microangiopathic hemolytic anemia
Teardrop cells	Pear-shaped erythrocytes visible on peripheral blood smear; indicative of mechanical stress on the RBC during release from the BM or passage through the spleen	Seen in a variety of conditions, including congenital anemias such as thalassemia and acquired disorders such as megaloblastic anemia; may also suggest a more ominous process such as myelophthisis (BM replacement)
Burr cells (echinocytes)	RBCs that have smooth undulations present on the surface circumferentially; pathogenesis unknown	Indicative of uremia when present on a properly made peripheral blood smear
Spur cells (acanthocytes)	RBCs that have spiny points present on the surface circumferentially; reflective of abnormal lipid composition of RBC membrane	Most commonly indicative of liver disease when present in significant numbers; also seen in abetalipoproteinemia and in RBCs lacking the Kell blood group antigen

BM, Bone marrow; *DIC,* disseminated intravascular coagulation; *G6PD,* glucose-6-phosphate dehydrogenase; *HUS,* hemolytic uremic syndrome; *RBC,* red blood cell; *TTP,* thrombotic thrombocytopenic purpura.

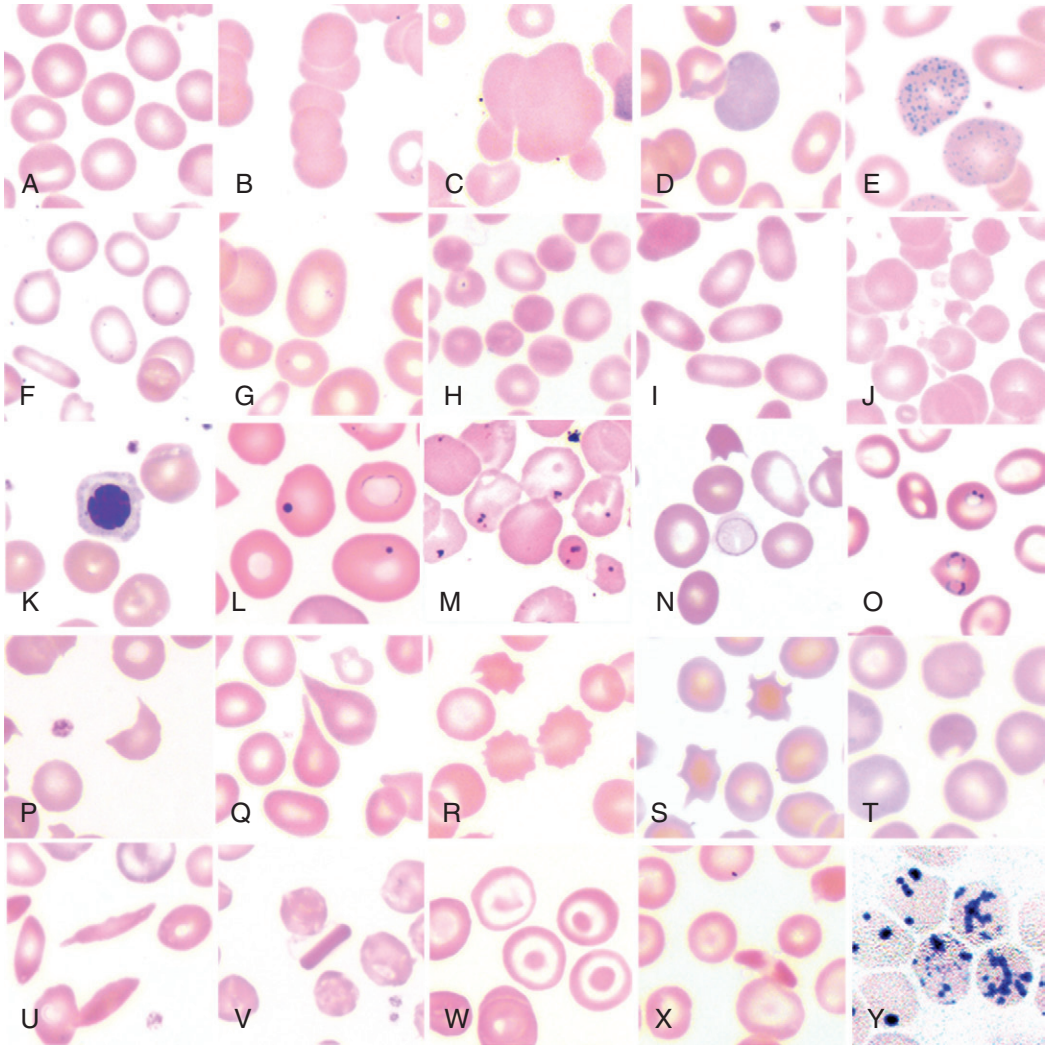

Figure 32-5 USEFUL PERIPHERAL BLOOD AND RED BLOOD CELL FEATURES IN THE EVALUATION OF ANEMIA. **A,** Normal red blood cells (RBCs). Note the central pallor is one-third the diameter of the entire cell. **B,** Rouleaux formation is indicative of increased plasma protein. **C,** Agglutination indicates an antibody-mediated process such as cold agglutinin disease. **D,** Polychromatophilic cell. The gray-blue color is attributable to RNA and the cell is equivalent to a reticulocyte, which must be identified with a reticulocyte stain. **E,** Basophilic stippling. This also is attributable to increased RNA caused either by a left shift in erythroid cells or lead toxicity. **F,** Hypochromic microcytic cells typical of iron-deficiency anemia. Note the widened central pallor and the "pencil" cell in the lower left. **G,** Macroovalocyte as can be seen in either megaloblastic anemia or myelodysplastic syndrome. **H,** Microspherocytes typical of hereditary spherocytosis. **I,** Elliptocytes (ovalocytes) from a patient with hereditary elliptocytosis. **J,** RBC fragments from thermal injury (burn patient). **K,** Nucleated RBC. **L,** Howell-Jolly bodies indicative of splenic dysfunction or absence. **M,** Pappenheimer bodies from a patient with sideroblastic anemia. **N,** Cabot ring, as can be seen in megaloblastic anemia or MDS. **O,** Malarial parasites *(Plasmodium falciparum)*. **P,** Schistocyte typical of a microangiopathic hemolytic anemia. **Q,** Tear-drop form indicates marrow fibrosis and extramedullary hematopoiesis. **R,** Echinocyte (Burr cell) with rounded edges. **S,** Acanthocyte (spur cell) with more irregular pointed ends. This was from a patient with neuroacanthocytosis. They can also be seen in patients with liver disease and lipid abnormalities. **T, "**Bite" cell from a patient with glucose-6-phosphate dehydrogenase (G6PD) deficiency. **U,** Sickle cell, from a patient with homozygous sickle cell disease. **V,** Hemoglobin C crystal. **W,** Target cells. **X,** Hemoglobin C disease. Note that the RBC in center has condensed hemoglobin at each pole. **Y,** Heinz body preparation (supravital stain) from a patient with G6PD deficiency. Note that the cells to the right have increased precipitated hemoglobin.

cytometry, cytogenetic analysis, fluorescence in situ hybridization (FISH), and molecular testing performed on the BM also can provide a wealth of diagnostic information.[28] Because of the discomfort involved in the procedure, however, careful consideration should be given to determining the array of tests required, so that repeated BM aspirates or biopsies need not be performed. If there is any consideration of the possibility of myelodysplasia, leukemia, or lymphoma, an aliquot of anticoagulated aspirate should be set aside at the time of the initial procedure that can be sent, if necessary, for flow cytometry or cytogenetics after review of the aspirate smear. It should be noted that even when properly performed, difficulty obtaining a BM aspirate is commonly observed in certain situations, including myelofibrosis, erythroblastic leukemia (M6), and hairy cell leukemia. In these cases, touch preps of the BM biopsy may help expedite diagnosis.

Diagnostic uncertainty in the setting of hypoproliferative anemia is an indication for BM biopsy. Hematologic disorders such as myelodysplasia, leukemia, lymphoma, or myeloma may be identified. Myelodysplasia in the marrow classically includes megaloblastic change and nuclear budding in maturing erythroblasts, as well as

Systematic Approach to the Diagnosis of Anemia

Integration of historic features and physical findings with thoughtful review of the results of the automated complete blood cell count and of the peripheral smear often serves to narrow down the differential diagnosis of anemia significantly. For example, a patient who has had a gastric bypass eating a normal diet who presents with gradual onset of fatigue accompanied by the more recent onset of distal paresthesias and a finding of decreased vibration sense in the setting of anemia with significantly elevated mean corpuscular volume and red blood cell distribution width values and numerous six-lobed polymorphonuclear leukocytes on peripheral blood smear almost certainly has vitamin B_{12} deficiency. This is suggested even before the return of specific laboratory testing because of the relatively narrow differential diagnosis for megaloblastic anemia and the fact that neurologic abnormalities are not associated with folate deficiency. For the purposes of diagnostic efficiency, the rewards of correlation of historic features and physical findings with a careful review of the peripheral blood smear cannot be overstated.

Special stains of the peripheral blood smear can be helpful in elucidating the cause of anemia. If there is significant nuclear debris present, the reticulocyte count obtained by automated methods can be inaccurate. In such cases, manual counting after staining with new methylene blue, which stains residual RNA in reticulocytes, permits accurate enumeration. If bite cells are detected on peripheral smear, supravital staining with methyl crystal violet can reveal Heinz bodies. These are aggregates of denatured hemoglobin reflecting an oxidative insult, most commonly caused by glucose-6-phosphate dehydrogenase deficiency or, less frequently, by the presence of an unstable hemoglobin (see Fig. 32-5, *H*).

morphologic abnormalities in other lineages, such as hypolobated megakaryocytes and hypogranulation of the myeloid lineage.[29] A variety of infiltrative (myelophthisic) processes may be observed.[30] These include malignancies such as small cell lung, breast, and prostate cancers, which frequently can appear in advanced stages with BM involvement. Alternatively, granulomas may be present, suggesting the possible presence of mycobacterial disease. In children, disseminated neuroblastoma and rhabdomyosarcoma occasionally can appear as a myelophthisic anemia.

FUTURE DIRECTIONS

Anemia may represent a primary hematologic disorder or may represent the manifestation of a systemic process. In children, the former tends to be somewhat more common than the latter, and in adults, the converse is true. However, in both children and adults, a systematic approach to the evaluation of anemia that includes careful review of historic features, the complete blood cell count, and peripheral smear facilitates an efficient diagnosis and minimizes unnecessary testing.

CHAPTER 33

PATHOPHYSIOLOGY OF IRON HOMEOSTASIS

Gary M. Brittenham

Iron is an essential element required for energy production, oxygen utilization, and cellular proliferation. Iron, able to act both as an electron donor and acceptor by readily interconverting between ferric (Fe^{3+}) and ferrous (Fe^{2+}) forms, is an irreplaceable component of oxygen transport (hemoglobin); storage (myoglobin); and sensing molecules, cytochromes, iron-sulfur clusters, and heme and nonheme enzymes. The ease with which iron can gain and lose electrons also makes iron able to catalyze the formation of highly reactive oxygen species that can damage lipids, protein and DNA, and injure subcellular organelles, resulting in cellular dysfunction, apoptosis, and necrosis. Consequently, both the total body iron and the amount within each cell are carefully controlled to assure adequate iron availability but avoid excess iron toxicity. Humans have no regulated means for iron excretion, and obligatory losses are normally minuscule, less than 0.05% of the total body iron each day. As a result, the amount of body iron is determined by control of iron absorption, and human iron homeostasis is distinguished by efficient recycling of iron (Fig. 33-1).

Although all cells require iron, quantitatively, most of the iron in the body is found within erythroid cells, and most of the daily movement of iron cycles through the erythroid compartment. External exchange of iron through absorption of iron from the gastrointestinal tract and from obligatory losses is very limited. Physiologically, iron is carried into the erythroid marrow and incorporated into hemoglobin and enters the circulation within red blood cells (RBCs) dedicated to oxygen transport. At the end of their lifespan, RBCs are phagocytized by a select population of macrophages in the bone marrow, liver, and spleen that then promptly render up most of the catabolized iron for return to the erythroid marrow. Any surplus is stored within macrophages or hepatocytes. After examining the intricate interrelation between intracellular and systemic iron homeostasis, this chapter considers in turn each portion of the pathway of iron transport, utilization, storage, and absorption (see Fig. 33-1). Altogether iron homeostasis is maintained by effective use of iron for erythropoiesis, efficient recycling of iron from senescent erythrocytes, controlled storage of iron by macrophages and hepatocytes, and careful regulation of intestinal iron absorption.[1]

REGULATION OF CELLULAR AND SYSTEMIC IRON HOMEOSTASIS

Each cell in the body needs iron in precise, carefully timed amounts for growth, development, and function. Within the systemic circulation, the varied and varying cellular requirements are met by the transport protein *transferrin*, the physiological carrier of iron through the plasma and extracellular fluid. Each cell obtains its share of circulating transferrin-bound iron by expressing *transferrin receptor 1*, a glycoprotein on cell membranes that binds the transferrin–iron complex and is internalized in an endocytic vesicle, where iron is released and then returns to the cell membrane, liberating apotransferrin into the plasma.[1-4] Within the cell, the iron released from the endosome is either used or sequestered with cytosolic *ferritin*, an iron storage protein that holds iron in a nontoxic form ready for prompt mobilization in time of need.[5] A prime determinant of the iron supply to each cell is the number of transferrin receptors expressed on the cell surface. Within each cell, iron self-regulates its intracellular availability, at least in part, translationally through the iron regulatory proteins (1 and 2) that function as sensors of intracellular iron (Fig. 33-2). The iron regulatory proteins recognize and bind to RNA stem–loop structures called iron responsive elements when iron is absent and dissociate when iron is present.[1-4] When the iron-responsive elements are within the 3′ untranslated region of a mRNA (e.g., transferrin receptor 1 mRNA), binding prevents mRNA degradation, increasing protein expression when iron is lacking. In contrast, when the iron-responsive elements are located in the 5′ untranslated region of an mRNA (e.g., cytosolic ferritin mRNA), binding of the iron regulatory proteins interferes with ribosomal assembly, decreasing protein expression when iron is absent. Accordingly, a *decrease* in intracellular iron availability enhances transferrin receptor 1 protein synthesis, increasing iron import, and reduces cytosolic ferritin protein production and iron storage. Conversely, an *increase* in intracellular iron availability reduces transferrin receptor 1 protein synthesis, inhibiting iron import, and augments cytosolic ferritin protein production and iron storage. In iron-replete cells, F box and leucine-rich repeat protein 5 (FBXL5), a subunit of a ubiquitin ligase complex, monitors cytosolic iron and leads to iron-dependent degradation of iron regulatory proteins.[6] Altogether, *regulation of intracellular iron homeostasis* is provided principally through the iron regulatory proteins by translational control of the synthesis of transferrin receptor and ferritin and, in some cells, other proteins involved in iron homeostasis, such as δ-aminolevulinic acid synthase 2 (eALAS), mitochondrial aconitase (ACO2), hypoxia inducible factor 2α (HIF-2α), intestinal divalent metal transporter 1 (DMT1) isoform I, and ferroportin.[1-4]

Regulation of systemic iron homeostasis is accomplished by control of the entry of iron into plasma for transport by transferrin.[1-4] Circulating transferrin iron is derived from specialized cells that can export iron, primarily reticuloendothelial macrophages that recycle iron from senescent RBCs, hepatocytes that can mobilize iron from stores, and duodenal enterocytes that provide iron absorbed from the diet. To enter plasma, iron in these cells must pass through *ferroportin*, a multitransmembrane-spanning protein that is the sole known cellular iron export channel.[7] *Hepcidin*, a small 25–amino acid peptide hormone secreted principally by the liver, provides posttranslational control of ferroportin expression by binding to and inducing its internalization, ubiquitination, and degradation, thereby inhibiting iron entry into plasma (Fig. 33-3).[7,8] Hepatic hepcidin synthesis is stimulated by increases in body iron stores, infection, inflammation, or malignancy and inhibited by hypoxemia and increased erythropoietic demand. Increments in plasma hepcidin reduce the amount of ferroportin in cell membranes, causing a prompt fall in plasma iron concentration. Conversely, decrements in plasma hepcidin concentration increase the amount of ferroportin, producing a rise in plasma iron concentration. Under conditions of iron deprivation, ferroportin can also (1) be posttranscriptionally regulated by iron-regulatory proteins binding to the 5′ iron-regulatory element in ferroportin mRNA and arresting synthesis and (2) be internalized and degraded in a hepcidin-independent manner requiring the E3 ubiquitin ligase Nedd4-2 and the Nedd4-2 binding protein Nfdip-1.[9]

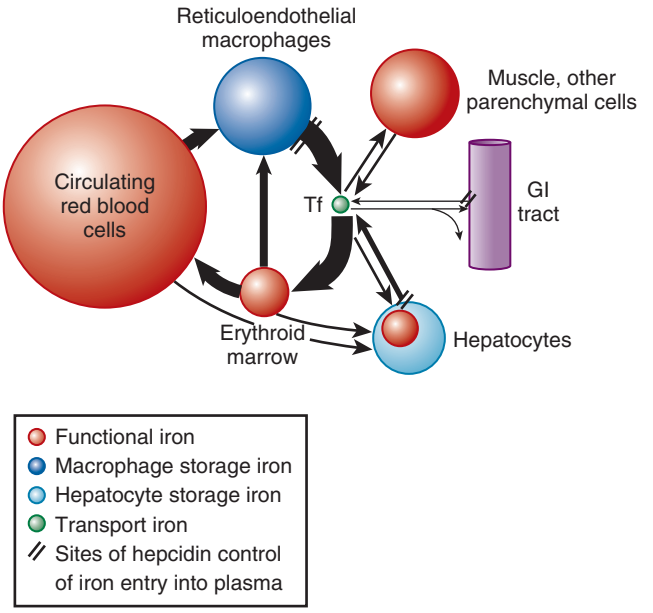

Figure 33-1 BODY IRON SUPPLY AND STORAGE. The figure shows a schematic representation of the routes of iron exchange in an adult. The area of each *circle* is proportional to the amount of iron contained in the compartment, and the width of each *arrow* is proportional to the daily flow of iron from one compartment to another. *Double slashes* indicate the sites of hepcidin action, decreasing macrophage release of iron derived from senescent red blood cells (RBCs), diminishing delivery of iron from duodenal enterocytes absorbing dietary iron, and inhibiting release of iron stored in hepatocytes. The concentration of iron in the human body is normally maintained at about 40 mg Fe/kg in women and about 50 mg Fe/kg in men. The major portion of iron is found in the erythron as hemoglobin iron (28 mg/kg in women; 32 mg/kg in men) dedicated to oxygen transport and delivery. Small amounts of erythron iron (<1 mg/kg) are also present in heme and nonheme enzymes in developing RBCs. The remainder of functional iron is found as myoglobin iron (4 mg/kg in women; 5 mg/kg in men) in muscle and as iron-containing and iron-dependent enzymes (1-2 mg/kg) throughout the cells of the body. Most storage iron (5-6 mg/kg in women; 10-12 mg/kg in men) is held in reserve by hepatocytes and macrophages. The small fraction of transport iron (≈0.2 mg/kg) in the plasma and extracellular fluid is bound to the protein transferrin (Tf). *GI,* Gastrointestinal.

UTILIZATION OF IRON FOR ERYTHROPOIESIS

Each day, almost 200 billion RBCs are produced in a normal adult to replace a similar number reaching the end of their lifespan. Each RBC contains more than a billion atoms of iron, four in each tetrameric molecule of hemoglobin, so that more than 200 quintillion (200×10^{18}) atoms of iron are needed daily for erythropoiesis. Transferrin transports iron in a nonreactive, soluble form in the circulation for delivery to erythroid precursors or other iron-requiring cells (Fig. 33-4). Apotransferrin, transferrin without attached iron, is a single-chain glycoprotein with two structurally similar lobes. Binding of a ferric ion to one of these lobes yields monoferric transferrin; binding of ions to both yields diferric transferrin. The transferrin saturation is the proportion of the available iron-binding sites on transferrin that are occupied by iron atoms, expressed as a percentage. In humans, almost all of the circulating plasma apotransferrin is synthesized by the hepatocyte. After delivering iron to cells, apotransferrin is promptly returned to the plasma to again function as an iron transporter, completing 100 to 200 cycles of iron delivery during its lifetime in the circulation. Apotransferrin is a true carrier that is not lost in delivering iron, so its turnover is unrelated to the plasma iron turnover; the half-life of the protein is about 8 days. In an iron-replete 70-kg man, the amount of transferrin-bound iron in the plasma at any given time is only about 3 mg, but more than 30 mg of iron moves through this transport compartment each day (see Fig. 33-1). Most (≈24 mg Fe/day) of the iron is used for erythropoiesis.

Transferrin receptors on the cell surface selectively bind mono- or diferric transferrin. Two different isoforms of the transferrin receptor exist, encoded by two separate genes. The two glycoproteins have similar extracellular structures but distinct roles in iron homeostasis. Transferrin receptor 1, ubiquitously expressed, functions as the physiologic transferrin iron importer on all iron-requiring cells. Transferrin receptor 2 is predominantly expressed on hepatocytes, functioning in the regulation of hepcidin expression (see later), and in developing erythroid cells, with a role in erythropoiesis (see later).[3,4] Transferrin receptor 1 is a transmembrane glycoprotein dimer composed of two identical subunits linked by a disulfide bond. Each transferrin receptor 1 can bind 2 molecules of transferrin; if each transferrin is diferric, the dimeric receptor can carry a total of 4 atoms of transferrin-bound iron. The affinity of transferrin receptor 1 for transferrin depends both on the iron content of transferrin and on the pH. With amounts of iron-bearing transferrin sufficient to saturate receptors at a physiologic pH of 7.4, transferrin receptor 1 has very little affinity for apotransferrin; an intermediate affinity for monoferric transferrin; and the highest affinity for diferric transferrin, estimated at 2 to 7×10^{-9} M. Under such physiological conditions, the affinity of transferrin receptor 1 for diferric transferrin is more than fourfold greater that for monoferric transferrin. At a pH of about 5, the affinity of transferrin receptor 1 for apotransferrin increases to that of diferric transferrin.

Iron delivery to an erythroid cell (see Fig. 33-4) begins with the binding of one or two molecules of mono- or diferric transferrin to a transferrin receptor 1.[1-4] The efficiency of iron delivery to the cell depends on the amounts of mono- and diferric plasma transferrin available. With normal erythropoiesis and a normal transferrin saturation of about 33%, the higher affinity of the receptor for diferric transferrin results in most of the iron supply to cells being derived from this form, providing four atoms of iron with each cycle. At a transferrin saturation of about 19%, equal amounts of iron are provided by mono- and diferric transferrin; at lower saturations, most of the iron is derived from the monoferric form. Whether mono- or diferric, the fate of transferrin bound to the transferrin receptor is the same. When bound, the iron-bearing transferrin–receptor complex rapidly clusters with other transferrin–receptor complexes in a clathrin-coated pit. When assembled, the clathrin-coated pit is promptly internalized and detaches from the inner membrane. Within the cytoplasm, the coated vesicle is rapidly stripped of clathrin, and the uncoated vesicles fuse to become multivesicular endosomes. Moving to the interior of the cell, a proton pump lowers endosome internal pH to about 5.6. In the acidic environment of the endosome, both transferrin and transferrin receptor 1 undergo conformational changes that enhance the rate and completeness of iron release. After release from transferrin within the acidified endosome as ferric iron, the iron is reduced by the ferrireductase six-transmembrane epithelial antigen of the prostate 3 (STEAP3) to the ferrous form and then transported across the endosomal membrane through the divalent metal transporter 1 (DMT1).[1] A DMT1-independent channel for ferrous iron, mucolipin 1 (TRPML1), has also been identified.[10] Acidification within the endosome increases the affinity of the now iron-free apotransferrin for the transferrin receptor with the result that the apotransferrin-receptor bond remains intact as the complex is transported back to the cell surface within the endosome. On exposure to the neutral pH of the plasma, the apotransferrin loses its affinity for the transferrin receptor and is released from the membrane, making both the apotransferrin and receptor available for reutilization (see Fig. 33-4).

Most of the iron transported across the endosomal membrane is directed to the mitochondria for use in the synthesis of heme (Fig. 33-4). Iron can be imported from the cytosol across the mitochondrial membrane by the transmembrane protein mitoferrin (SLC25A37).[3,4] Transport of iron from endosomes into mitochondria for heme synthesis by direct contact between the organelles, avoiding the cytosol, also has been proposed.[11] Heme (ferrous protoporphyrin

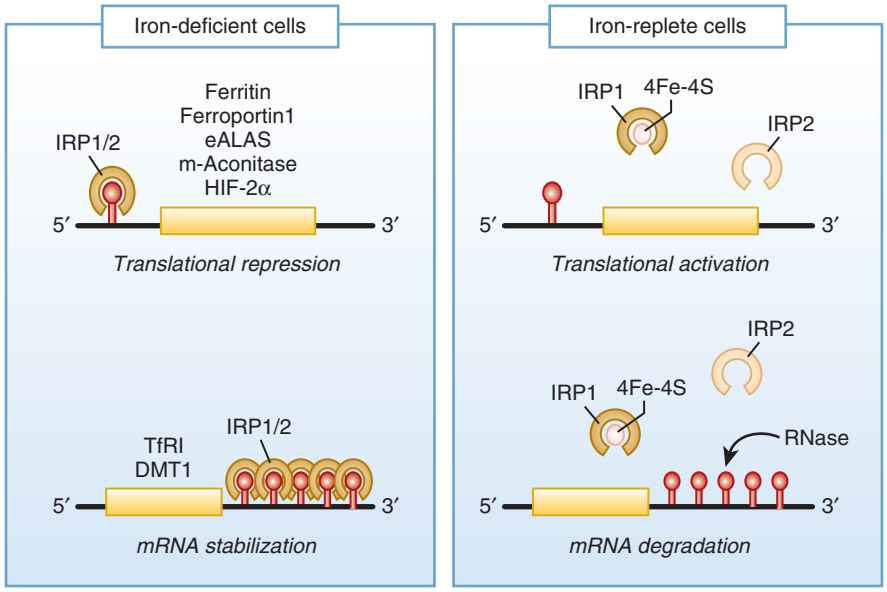

Figure 33-2 REGULATION OF CELLULAR IRON HOMEOSTASIS BY THE IRON REGULATORY PROTEINS (IRP1 AND IRP2). The iron regulatory proteins recognize and bind to RNA stem-loop structures called iron responsive elements (IREs) when iron is absent and dissociate when iron is present. Binding IREs within the 3′ untranslated region of mRNA (e.g., transferrin receptor 1 [TfR1]) and some intestinal divalent metal transporter 1 (DMT1) isoforms increases mRNA stability, increasing protein synthesis. In contrast, binding IREs in the 5′ untranslated region of mRNA (e.g., cytosolic ferritin, ferroportin1 [FPN1A], erythroid aminolevulinic acid synthase [eALAS], mitochondrial aconitase [m-aconitase], and hypoxia-inducible factor 2α [HIF-2α]) inhibits protein expression when iron is absent. In iron-replete cells, IRP1 assembles a cubane Fe/S cluster, acquiring aconitase activity while losing the ability to bind to IREs. In iron-replete cells, IRP2 interacts with F box and leucine-rich repeat protein 5 (FBXL5), a subunit of a ubiquitin ligase complex, leading to its ubiquitination and degradation by the proteasome. See text for details. *(Modified with permission from Wallander ML, Leibold EA, Eisenstein RS: Molecular control of vertebrate iron homeostasis by iron regulatory proteins.* Biochim Biophys Acta *1763:668, 2006.)*

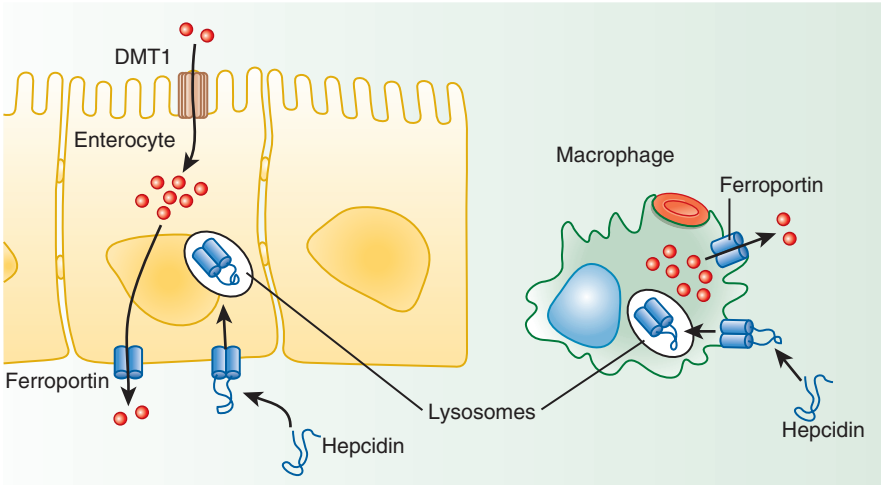

Figure 33-3 CONTROL OF IRON ENTRY INTO PLASMA BY FERROPORTIN AND HEPCIDIN IN THE REGULATION OF SYSTEMIC IRON HOMEOSTASIS. Ferroportin, a multitransmembrane-spanning protein that is the only known iron exporter in humans, is expressed at high concentrations on the basolateral membrane of duodenal enterocytes, reticuloendothelial macrophages, and hepatocytes (not shown). Plasma hepcidin binds to a specific extracellular domain of ferroportin, inducing the binding and then autophosphorylation of cytosolic Janus kinase 2 (JAK2). JAK2 then phosphorylates ferroportin, leading to ferroportin internalization by clathrin-coated pits and its subsequent degradation in the lysosome. See text for details. *DMT1,* Divalent metal transporter 1. *(Modified with permission from Andrews NC: Forging a field: the golden age of iron biology.* Blood *112:219, 2008.)*

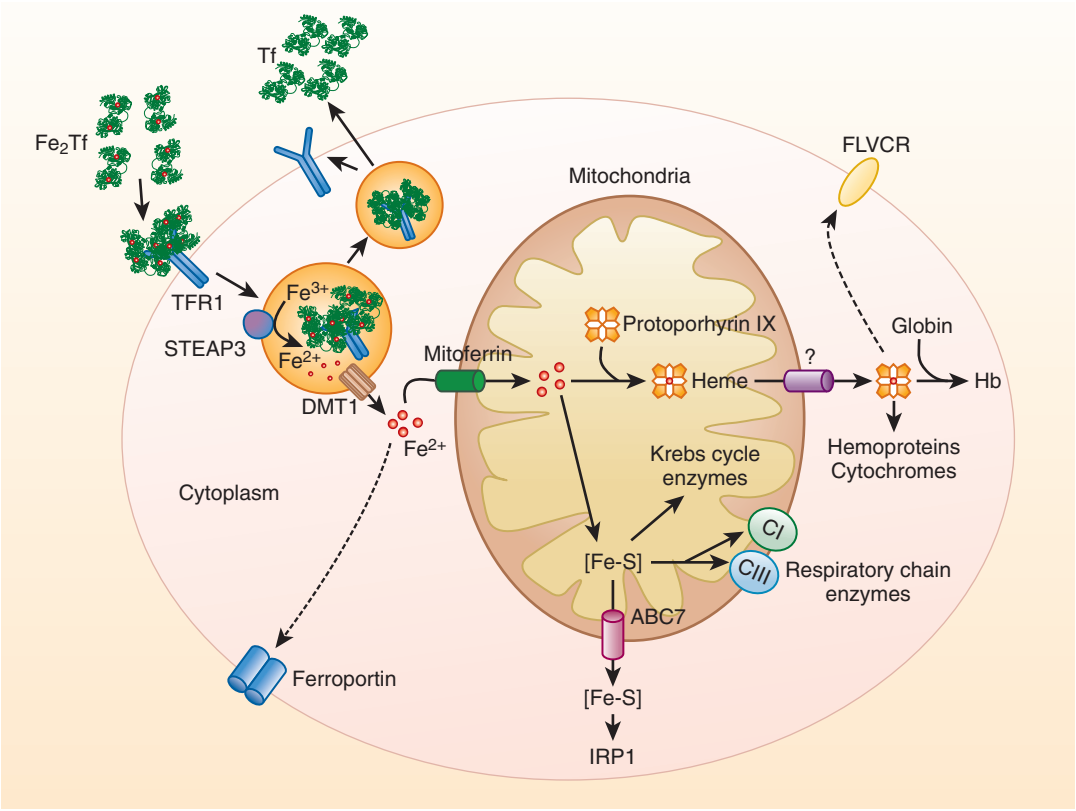

Figure 33-4 ACQUISITION AND UTILIZATION OF IRON BY ERYTHROID PRECURSORS. Iron is imported in the transferrin (Tf) cycle and principally used for the synthesis of heme. IX), a planar molecule consisting of an atom of ferrous iron in the center of a tetrapyrrole ring, is then synthesized in eight biochemical reactions with the first and final three reactions catalyzed by mitochondrial enzymes and the four intermediate reactions taking place in the cytoplasm. Most heme is then bound to α- or β-globin subunits that combine to form α-β dimers that in turn join to form the functional α_2-β_2-tetramer of hemoglobin (see Fig. 33-4). Small amounts of heme are incorporated into heme enzymes and cytochromes. The fraction of iron not used for heme synthesis can assembled into iron sulfur clusters both within mitochondria and in the cytosol (see Fig. 33-4). The cytosolic iron chaperone poly (rC) binding protein 1 (PCBP1) may iron that is in excess of erythroid requirements for heme synthesis to cytosolic ferritin for storage.[5,12] The same iron chaperone may also carry iron to some cytosolic nonheme enzymes.

Erythroid precursors have a number of mechanisms to adapt to either inadequate or overabundant supplies of iron. First, the rate of erythropoiesis is coordinated with iron availability by iron regulation of erythroid differentiation. Iron deficiency reduces the responsiveness of erythroid progenitors to erythropoietin (EPO), apparently through an iron–aconitase–isocitrate pathway.[13] With a dearth of iron, decreased erythroid utilization for RBC production helps preserve the supply of iron for vital functions in other tissues. Second, transferrin receptor 2 is a component of the EPO receptor complex that is required for efficient erythropoiesis and is involved in the production of growth differentiation factor (GDF-15), a putative regulator of hepatic hepcidin synthesis (see later discussion).[14] Third, heme synthesis is coordinated with iron availability through an iron regulatory element in the 5′ untranslated region of the mRNA for δ-aminolevulinic acid synthase 2 (eALAS), the erythroid-specific initial enzyme in the heme synthetic pathway. If intracellular iron availability is low, binding of an iron regulatory protein will inhibit heme synthesis by preventing translation of the mRNA.[3] Fourth, if a lack of iron leads to heme deficiency, the heme-regulated translational inhibitor (HRI) is activated and, acting through the α-subunit of eukaryotic initiation factor 2 (eIF2α), halts protein synthesis to coordinate the translation of globin mRNAs with the intracellular heme concentration.[15] This action of the heme-regulated translational inhibitor is responsible for the physiological adaptation that produces hypochromic, microcytic erythrocytes in iron deficiency. Fifth, developing erythroblasts synthesize ferroportin to export iron. Their expression of ferroportin is regulated principally by hepcidin, providing another means to coordinate erythroid iron utilization with systemic iron availability. In erythroid precursors (and in duodenal enterocytes; see later discussion), two ferroportin transcripts are present: the ubiquitously expressed FPN1A, with an iron-responsive element in its 5′ untranslated region, and FPN1B, which lacks the iron-responsive element.[16] During erythroid cell differentiation, FPN1B expression circumvents translational repression through the iron responsive element, iron regulatory protein system, thereby permitting export of iron from erythroid precursor cells during the critical time period when cells commit to proliferation and differentiation, express high levels of transferrin receptor 1, and rapidly accumulate iron. As a consequence, erythropoiesis may be partially suppressed when nonerythropoietic tissues risk developing iron deficiency. Iron export from erythroblasts via FPN1B may account for the development of iron deficiency anemia as an initial, early manifestation of systemic iron deficiency.[16] Nonetheless, when the cells begin to produce hemoglobin, FPN1B expression diminishes, and FPN1A predominates, allowing erythroid cells to limit iron export through the iron-responsive element iron regulatory protein system and to efficiently manufacture heme.[16] Sixth, as noted earlier, cytosolic

ferritin can be synthesized to sequester surplus iron accumulations in a safe and soluble form.[5] Seventh, a mitochondrial ferritin, consisting of homopolymers of a nuclear gene-encoded H-type ferritin (see later), can be expressed to protect against mitochondrial iron accumulation in sideroblastic anemia and some other disorders.[5] Eighth, erythroblasts have the capacity to export excess heme through the feline leukemia virus subgroup C cellular receptor (FLVCR) and avoid heme toxicity.[17]

Orthochromatic erythroblasts, with nuclei that are unable to synthesize DNA, gradually lose most mitochondria and halt RNA synthesis but continue to produce hemoglobin. The pyknotic nucleus is finally extruded through the erythroblast membrane with the loss of about 5% to 10% of the hemoglobin that had been synthesized previously. The resultant reticulocyte continues to synthesize hemoglobin for another 2 to 3 days until the cellular supply of mRNA is exhausted, producing as much as 30% of the total hemoglobin complement of the RBC. Eventually, the reticulocyte is released from the marrow, remodeled, and pitted of siderotic granules and debris within the spleen to emerge as a mature RBC dedicated to oxygen delivery over its lifespan of 3 to 4 months.

RECYCLING OF ERYTHROCYTE IRON BY MACROPHAGES

The major pathway of iron movement from erythroid cells is to a dedicated population of macrophages in the bone marrow, liver (Kupffer cells), and spleen as RBCs reach the end of their lifespan (Fig. 33-5). Macrophages in the bone marrow also have the responsibilities of culling defective immature erythroid cells to prevent their release into the circulation and of removing some deposits of erythrocyte ferritin from developing RBCs. During their time in the bloodstream, RBCs undergo a multitude of modifications (oxidant damage, metabolic depletion, increasing intracellular calcium concentrations, dehydration, decrease in cell volume, phosphatidylserine exposure, formation of "senescent" antigens, and others) that lead to their recognition and selective removal by specialized macrophages in the bone marrow, liver, and spleen.[18] On average, each of these macrophages can phagocytize one erythrocyte a day. After ingesting the erythrocyte in a phagosomal vacuole known as an erythrophagolysosome, the erythrocyte membrane is lysed. The hemoglobin within then undergoes oxidative precipitation and rapid catabolism into heme (see Fig. 33-5).[2]

A small proportion of aged or damaged erythrocytes undergo intravascular hemolysis. With normal erythropoiesis, this portion of the total iron flux is minor but can increase substantially in disorders with increased ineffective erythropoiesis or intravascular hemolysis. The hemoglobin released into plasma by is then rapidly bound by haptoglobin, a glycoprotein synthesized in the liver.[2] The hemoglobin–haptoglobin complex (M_r 150,000) is too large to be filtered by the kidneys, a feature that helps restrict the renal loss of iron with hemoglobinemia. Macrophages (and hepatocytes; see later) remove the haptoglobin–hemoglobin complex from plasma by binding through the CD163 receptor and after endocytosis digest the complex in lysosomes, liberating heme. In an analogous fashion, any heme released into plasma by intravascular hemolysis complexes with hemopexin and is removed by macrophages (and hepatocytes) expressing the CD91 receptor.[2] In macrophages, heme from all these sources is degraded by an enzymatic complex containing NADPH

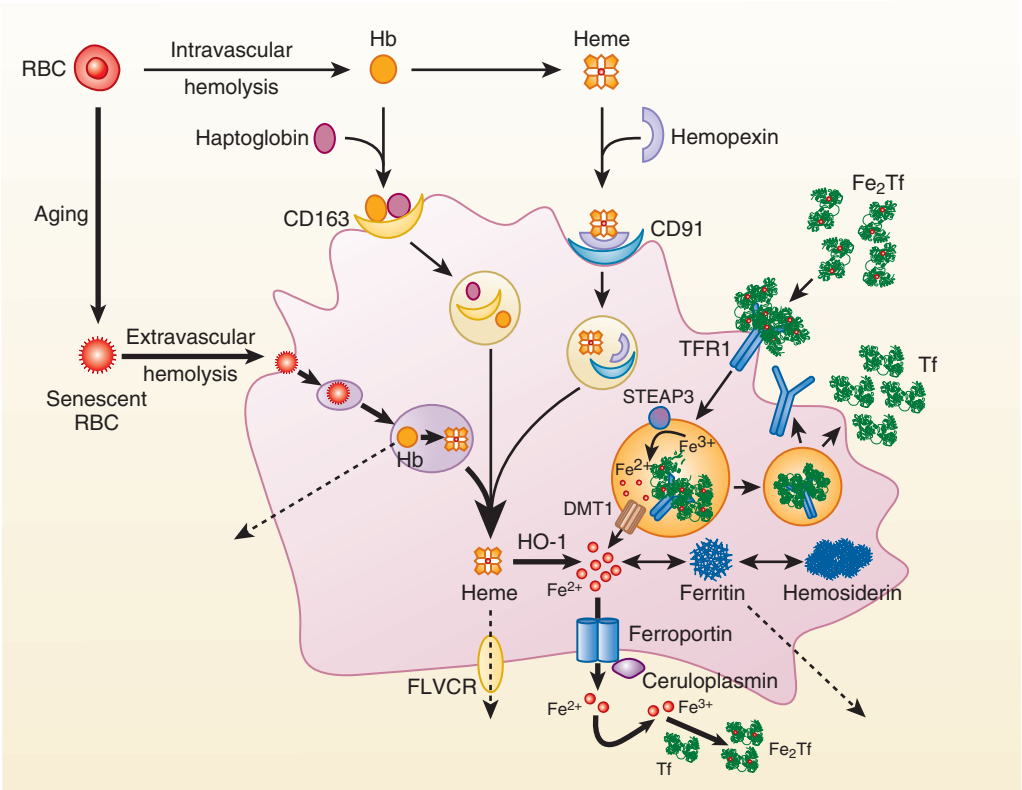

Figure 33-5 RECYCLING OF ERYTHROCYTE IRON BY MACROPHAGES. Most erythrocyte iron is acquired by erythrophagocytosis of senescent red blood cells (RBCs), but smaller amounts are derived from hemoglobin–haptoglobin and heme–hemopexin complexes. Iron derived from plasma transferrin (Tf) is a minor portion of the total iron flux. Heme is catabolized, and the iron exported through ferroportin and oxidized by ceruloplasmin. In the absence of iron deficiency, a portion of the iron is retained as ferritin and hemosiderin. See text for details. *DMT1,* Divalent metal transporter 1; *Fe_2Tf,* diferric transferrin; *FLVCR,* feline leukemia virus subgroup C cellular receptor; *Hb,* hemoglobin; *HO-1,* heme oxygenase-1; *TFR1,* transferrin receptor 1; *STEAP3,* six-transmembrane epithelial antigen of the prostate 3. *(Modified with permission from Beaumont C, Delaby C: Recycling iron in normal and pathological states.* Semin Hematol *46:328, 2009.)*

(nicotinamide adenine dinucleotide phosphate)–cytochrome c reductase, the microsomal enzyme heme oxygenase 1, and biliverdin reductase, yielding carbon monoxide (the sole physiological source in the body), bilirubin, and iron (see Fig. 33-5). Both DMT1 and natural resistance-associated macrophage protein 1 (NRAMP1), a divalent metal transporter expressed within the late endosomal and phagolysosomal membranes of iron-recycling macrophages, seem to be involved in efficient recycling of this iron.[19] Macrophages also can acquire iron from plasma transferrin via the transferrin cycle, but this is a minor portion of their total iron flux.

Ferroportin is the conduit for the outpouring of iron from macrophages in the bone marrow, liver, and spleen to plasma apotransferrin, normally the largest single flux of iron from cells in the body. Ferroportin transcription increases in response to both iron and heme.[9] Ferroportin (FPN1A) levels are also regulated posttranscriptionally through an iron-responsive element in the 5′ untranslated region, with increases in cytosolic iron resulting in increased ferroportin translation. Iron export through ferroportin requires ferroxidase activity, provided by the multicopper oxidase ceruloplasmin in macrophages and by hephaestin in duodenal enterocytes (see later). Ceruloplasmin oxidation may generate a concentration gradient that drives the ferric iron out of the macrophage.[7] In the absence of ceruloplasmin, macrophage ferroportin is rapidly internalized and degraded.[7] Unsaturated transferrin is not required for the release of iron from the macrophages; apotransferrin does not enter the macrophage and accepts iron only after the exit of iron through ferroportin and oxidation by ceruloplasmin. The ferric iron can then be bound by transferrin and transported back to erythroid and other iron-requiring tissues.

Plasma hepcidin regulates iron efflux from macrophages by decreasing the number of ferroportin channels available for iron export. Ferroportin is a dimer, and each monomer must bind hepcidin for internalization, ubiquitination, and degradation to occur.[7] Hepcidin binding to ferroportin is followed by the binding of Janus kinase 2 (JAK2), a tyrosine kinase; each monomer of ferroportin binds a single JAK2. The bound JAK2 is autophosphorylated, and phosphorylated JAK2 in turn phosphorylates ferroportin, which is subsequently internalized in clathrin-coated pits. Ferroportin is then ubiquitinated and enters the multivesicular body that fuses with lysosomes for ferroportin degradation. The requirement for the cooperative interaction of the two subunits explains the autosomal dominant inheritance of ferroportin mutations responsible for iron overload (see Chapter 34).[7] For the most part, these mutations either interfere with iron export by decreasing the amount of functional ferroportin on the cell surface, resulting in retention and accumulation of macrophage iron, or produce ferroportin resistance to internalization and degradation by hepcidin, resulting in loss of control of macrophage iron export that leads to parenchymal iron loading.[7] Homozygous ferroportin mutations are likely lethal.

Under normal circumstances, the macrophages in the liver, spleen, and bone marrow that are dedicated to reprocessing hemoglobin iron from senescent erythrocytes maintain an equilibrium between iron storage and release. Synthesis of cytosolic ferritin is induced in response to erythrophagocytosis and, in the absence of iron deficiency, a portion of the iron derived from the ingested erythrocyte is retained within the macrophage as soluble cytosolic ferritin. With increasing amounts of storage iron within the macrophage, an increasing proportion of iron is stored within amorphous, insoluble masses as hemosiderin (see later). Based on studies with heat-damaged erythrocytes labeled with radioactive iron, the fraction of radioiron sequestered within the macrophage can vary from virtually none in association with iron deficiency to a maximum of almost 80% in the presence of bone marrow aplasia and a fully saturated plasma transferrin.

LIVER IRON STORAGE AND REGULATION OF SYSTEMIC IRON HOMEOSTASIS

The liver is both a major iron storage organ, sequestering iron in cytosolic ferritin and hemosiderin within hepatocytes and macrophages (Kupffer cells), and, as the principal source of plasma hepcidin, the central site for control of systemic iron homeostasis. The dual blood supply of the liver from the portal and systemic circulation may be an important feature, allowing monitoring of both plasma iron in the systemic circulation and newly absorbed iron in the portal circulation.[3] Hepatocytes can acquire iron from plasma transferrin via the transferrin cycle, from hemoglobin–haptoglobin and heme–hemopexin complexes via endocytosis after binding to CD163 and CD91 receptors, respectively; from lactoferrin, apparently by receptor-mediated endocytosis; and from plasma non–transferrin-bound iron (Fig. 33-6). Plasma non–transferrin-bound iron forms when the rate of iron influx into plasma exceeds the rate of iron acquisition by transferrin.[20] Plasma non–transferrin-bound plasma iron enters specific cells independently of the transferrin mechanism, particularly hepatocytes, cardiomyocytes, anterior pituitary cells, and pancreatic β cells, producing toxic accumulations in some forms of iron overload (see Chapter 34).[21] The specific routes for cellular uptake of plasma non–transferrin-bound iron have not been identified with certainty but may include divalent metal transporter 1 (DMT1), ZRT/IRT-like protein 14 (ZIP14), and L-type calcium channels.[3]

Within hepatocytes and other cells, cytosolic iron is present physiologically in low-molecular-weight forms destined for incorporation into functional compounds or, if present in amounts exceeding cellular requirements, for storage. As noted earlier, a cytosolic iron chaperone, poly (rC)-binding protein 1 (PCBP1),[12] delivers excess iron to ferritin, whose structure maintains large amounts of iron in solution in a compact yet bioavailable form, diffusely distributed within the cytosol. Cytosolic ferritin is a heteropolymer consisting of 24 subunits of heavy (H) and light (L) peptides that form a hollow sphere into which as many as 4500 atoms of iron may be deposited in an iron core composed of the hydrous ferric oxide mineral ferrihydrite ($5Fe_2O_3{\cdot}9H_20$).[5] Recent studies indicate that iron entry and exit from ferritin are in an equilibrium with the concentration of cytosolic iron.[22] Both uptake and release of iron appear to be intrinsic, autonomous properties of the ferritin molecule. When cytosolic iron is low, iron-containing ferritin particles are randomly dispersed in the cytoplasm. As cytosolic iron increases, concentrations of dispersed ferritin rise, and small clusters of ferritin begin to appear, still soluble and spread throughout the cytosol. With further increases in cytosolic iron, ferritin enters lysosomes by fusion of ferritin clusters with lysosomal membranes, by autophagocytosis, or both, forming siderosomes. Catabolism of ferritin within siderosomes leads to denaturation of ferritin protein subunits and aggregation of the ferritin iron cores, resulting in the formation of amorphous, insoluble masses of hemosiderin. If the extent of iron overload overwhelms the capacity of ferritin to store iron, ferritin iron may act as a pro-oxidant contributing to tissue injury. Production of hemosiderin seems to help protect against iron toxicity by sequestering the excess iron away from the cytosol, enclosed within siderosome membranes. As the total amount of tissue iron increases, the proportion stored as hemosiderin rises, from trace amounts in normal individuals to 90% or more with severe iron overload. Depending on the cellular type and iron supply and use, the half-life of cellular ferritin may range from less than 20 to 96 hours. Hemosiderin characteristically has a much slower cellular turnover than ferritin. Altogether, for short-term storage of iron, cytosolic iron is in rapid equilibrium with soluble, dispersed ferritin,[22] but for long-term sequestration, the aggregates of iron within hemosiderin undergo slow and limited exchange. Nonetheless, with phlebotomy or iron-chelating therapy, all of the iron within hemosiderin deposits eventually can be mobilized.

The liver functions as the central controller of systemic iron homeostasis by being the predominant synthetic source of hepcidin. The biologically active 25–amino acid peptide is produced by proteolytic processing of an 84–amino acid prepropeptide by furin.[8] After secretion, hepcidin circulates in plasma bound to α2-macroglobulin and is rapidly cleared by the kidneys or degraded after binding to ferroportin. As detailed earlier, hepcidin controls the entry of iron into plasma by decreasing the number of ferroportin channels available for iron export from macrophages, hepatocytes, and

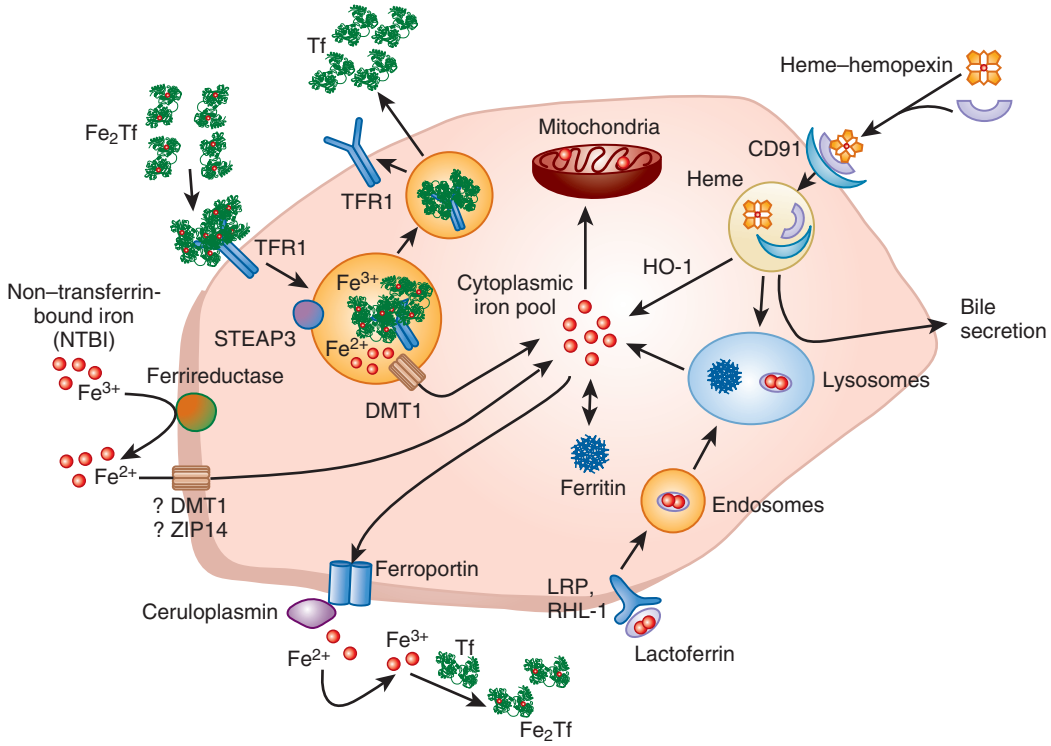

Figure 33-6 ACQUISITION, UTILIZATION, STORAGE, AND EXPORT OF IRON BY HEPATOCYTES. Hepatocytes can acquire iron from plasma transferrin (Tf) via the Tf cycle; from heme–hemopexin complexes via endocytosis after binding to CD91 receptors from lactoferrin, apparently by receptor-mediated endocytosis; and from plasma non–Tf-bound iron (NTBI). Iron is used for synthesis of heme and nonheme enzymes, with any excess stored in ferritin and hemosiderin. Iron is exported through ferroportin and oxidized by ceruloplasmin before being taken up by plasma Tf. See text for details. *DMT1,* Divalent metal transporter 1; *Fe_2Tf,* diferric transferrin; *FLVCR,* feline leukemia virus subgroup C cellular receptor; *HO-1,* heme oxygenase-1; *LRP,* low-density lipoprotein receptor-related protein; *RHL-1,* rat hepatic lectin-1 subunit of the asialoglycoprotein receptor; *STEAP3,* six-transmembrane epithelial antigen of the prostate 3; *TFR1,* transferrin receptor 1; *ZIP14,* Zrt- and Irt-like protein 14 (SLC39A14, solute carrier family 39, member 14). *(Modified from Graham RM, Chua ACG, Herbison CE, et al: Liver iron transport.* World J Gastroenterol *13:4725, 2007.)*

duodenal enterocytes. Plasma hepcidin concentrations increase with elevations in iron in plasma and in hepatocytes, and with infection and inflammation, decreasing plasma iron. Plasma hepcidin concentrations decrease with iron deficiency, hypoxia, and increased erythropoietic requirements for iron, increasing plasma iron.[8] The hepatocyte coordinates the congruent or conflicting influences of iron, infection, and erythropoietic demand to determine hepcidin secretion and thereby the systemic supply of iron. Because the amount of plasma iron is small and is replaced every 2 to 3 hours, changes in plasma hepcidin are followed rapidly by changes in plasma iron.

Regulation of hepcidin seems to be entirely transcriptional,[8] integrating signals for induction and inhibition of synthesis both from within and outside the hepatocyte. Intensive investigation has revealed a complex signaling network for transcriptional regulation of hepcidin[23] (summarized graphically in Fig. 33-7) that remains incompletely characterized and with some features that still require verification in human studies. The available evidence indicates that hepatic hepcidin synthesis is regulated by iron (hepatic iron stores, dietary iron, plasma iron in the systemic circulation), erythropoietic iron requirements, and inflammation and endoplasmic reticulum (ER) stress.[3,7,8,23,24]

Iron Regulation of Hepcidin Expression

Bone morphogenetic protein 6 (BMP6), a member of the transforming growth factor-β (TGFβ) superfamily, is the key endogenous regulator of hepcidin production (see Fig. 33-7). BMP6 seems to be primarily produced (1) by liver nonparenchymal cells in response to hepatocyte iron stores[4] and (2) by duodenal enterocytes in response to dietary iron.[25] BMP6 initiates a signaling cascade by binding to hemojuvelin, a membrane glycophosphatidlyinositol-linked BMP coreceptor essential for effective induction of hepcidin, and to BMP receptors on the surface of hepatocytes. BMP6 binding is followed by phosphorylation of sons of mothers against decapentaplegic (SMAD)1/5/8 and formation of the SMAD1/5/8–SMAD4 complex, which translocates to the nucleus and activates the promoter of the hepcidin gene (*HAMP*).[3,8,23,24] SMAD7 interferes with BMP6-HJV-SMAD–mediated hepcidin activation.[3] Hemojuvelin is a critical potentiator of the BMP6-SMAD regulatory pathway. Mutations in *HJV*, the gene for hemojuvelin, and in *HAMP* almost abolish synthesis of hepcidin, resulting in juvenile forms of hemochromatosis (types 2A and 2B, respectively; see Chapter 34) with severe iron loading. Neogenin, a DCC (deleted in colorectal cancer) family member, seems to stabilize hemojuvelin, thereby enhancing BMP6 signaling and hepcidin expression.[3,23] Furin, a proprotein convertase, cleaves membrane-bound hemojuvelin to produce a soluble form of hemojuvelin that acts as a competitive antagonist of membrane-bound HJV, inhibiting hepcidin activation.[3,23] TMPRSS6, a transmembrane serine protease, inhibits BMP6 induction of hepcidin synthesis by cleaving hemojuvelin from the cell membrane.[26] Inactivating mutations in the gene *TMPRSS6* produce high levels of hepcidin that are responsible for iron-refractory iron-deficiency anemia (see Chapter 34).[27]

Plasma iron, probably as diferric transferrin, is believed to modulate hepcidin synthesis through a distinct pathway that

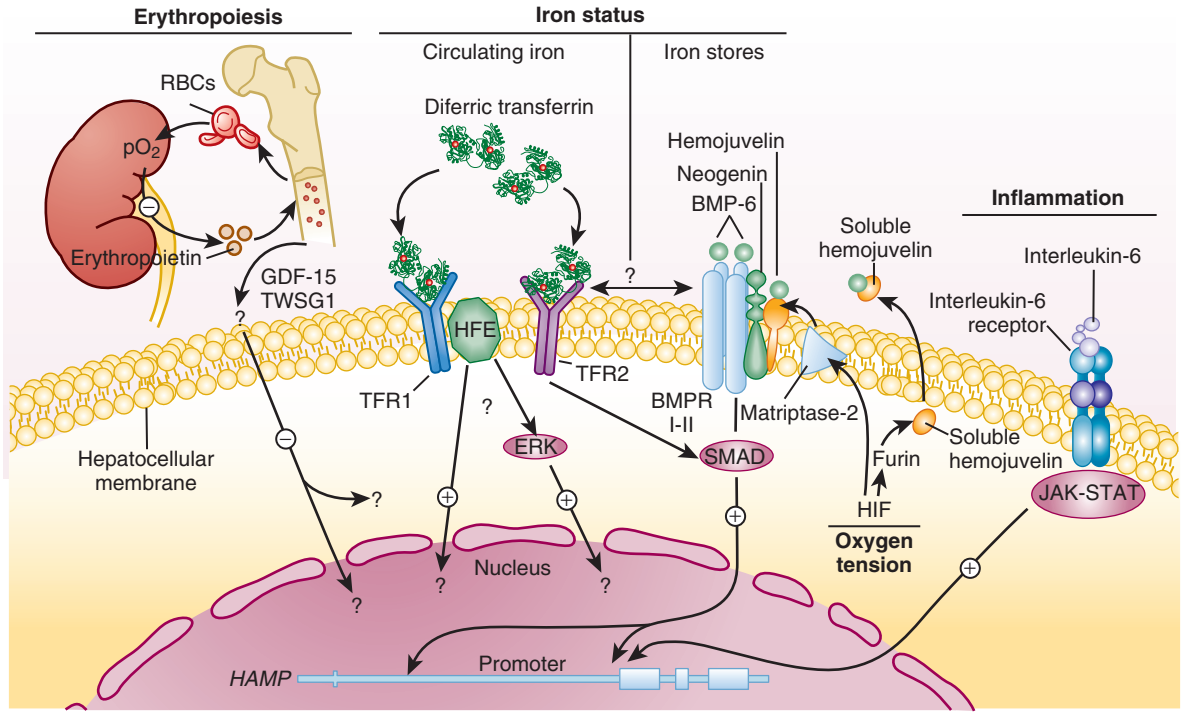

Figure 33-7 TRANSCRIPTIONAL REGULATION OF HEPCIDIN EXPRESSION IN HEPATOCYTES. Hepatic hepcidin synthesis is regulated by iron, erythropoietic iron requirements, inflammation, and endoplasmic reticulum (ER) stress. Bone morphogenetic protein 6 (BMP6) is the key endogenous regulator of hepcidin synthesis. BMP6 initiates a signaling cascade by binding to the BMP coreceptor hemojuvelin and to two type I and two type II BMP receptors (BMPR I-II) on the surface of hepatocytes. Neogenin may act to stabilize hemojuvelin. BMP6 binding is followed by phosphorylation of sons of mothers against decapentaplegic (SMAD)1/5/8 and formation of the SMAD1/5/8–SMAD4 complex, which translocates to the nucleus and activates the promoter of the hepcidin gene (*HAMP*). The soluble form of hemojuvelin, cleaved by furin, seems to compete for BMP binding with membrane-anchored hemojuvelin. SMAD7, stimulated by iron, interferes with SMAD4 hepcidin activation. TMPRSS6 (transmembrane protease, serine 6; matriptase-2) inhibits BMP6 induction of hepcidin synthesis by cleaving hemojuvelin from the cell membrane. HFE (the hemochromatosis protein) interacts with TfR1 and likely also with TfR2 to modulate hepcidin synthesis through the BMP6-HJV-SMAD pathway and, possibly, through alternative routes involving the extracellular signal–regulated kinase 1 and 2 (ERK1/2), mitogen-activated protein (MAP) kinases, and furin. Erythropoietin (EPO), growth differentiation factor15 (GDF15), and twisted gastrulation (TWSG1), have been proposed as mediators of hepcidin suppression by erythropoietic iron demand but the erythroid factors involved remain uncertain. The inflammatory cytokine IL6 induces hepcidin expression through a Janus kinase (JAK) signal transducer and activator of transcription (STAT) signaling pathway. Other cytokines and the BMP6-HJV-SMAD pathway may also be involved along with ER stress (not shown), possibly mediated by the transcription factor cyclic AMP response element–binding protein H (CREBH) or by the stress-inducible transcription factors CCAAT/enhancer-binding protein (C/EBP) homologous protein (CHOP) and CCAAT-enhancer-binding protein-alpha (C/EBPα). See text for details. *HIF,* Hypoxia inducible factor; *RBC,* red blood cell. *(Modified from Fleming RF, Ponka P. involves HFE, an atypical major histocompatibility complex class I protein that forms a complex with β2 microglobulin, and transferrin receptor 2 (see Fig. 33-7).[1,3,4,23] Mutations in the genes encoding these proteins, *HFE* (hemochromatosis gene) and *TFR2* (transferrin receptor 2 gene), respectively, are responsible for adult forms of hemochromatosis (types 1 and 3, respectively; see Chapter 34). In these adult forms of hemochromatosis, hepcidin is expressed but fails to be appropriately upregulated as iron stores increase; iron loading is generally less severe than in the juvenile forms. The means whereby these proteins influence hepcidin synthesis are uncertain but may involve binding of circulating diferric transferrin to transferrin receptor 1, displacing HFE to form a complex with diferric transferrin receptor 2. The complex then acts through the BMP6-HJV-SMAD pathway, alternative routes involving the extracellular signal–regulated kinase 1 and 2 (ERK1/2), mitogen-activated protein kinases, and furin, or some combination of these and other pathways.[3,23] Another level of control has been reported that involves a microRNA, short nucleotide hairpin loops that can interact in a complex with complementary sequences in the 3′- untranslated region of mRNA transcripts. The microRNA miR-122 binds to *HFE* and *HJV* mRNA, apparently increasing hepcidin expression.[28]

Erythropoietic Regulation of Hepcidin Expression

Increased erythropoietic demand for iron decreases hepatic hepcidin synthesis in a dominant manner that can override influences inducing hepcidin expression, such as iron overload and inflammation (see later). Patients with marked ineffective erythropoiesis, such as those with β-thalassemia intermedia, have very low or absent plasma hepcidin, increased iron absorption, and high plasma iron despite severe iron overload. Anemia and hypoxia decrease hepcidin expression, but these effects seem to be principally mediated by erythropoietic activity. In animal models, ablation of the erythroid bone marrow abolishes the effect of anemia. HIF-2 is apparently not involved. EPO, growth differentiation factor15 (GDF15), and twisted gastrulation

(TWSG1) (see Fig. 33-7) have been proposed as mediators of hepcidin suppression, but definitive identification of the erythroid factors involved is lacking.[3,4,23]

Inflammatory and Endoplasmic Reticulum Stress–Related Regulation of Hepcidin Expression

Inflammation increases plasma hepcidin, resulting in retention of iron within macrophages, reduced iron absorption, and hypoferremia.[8] The inflammatory cytokine interleukin-6 (IL-6) induces hepcidin expression (see Fig. 33-7). IL-6 activates the JAK signal transducer and activator of transcription (STAT) signaling pathway, stimulating hepcidin production through STAT3 interactions with a STAT3-binding element in the hepcidin promoter.[8,29] Other cytokines and the BMP6-HJV-SMAD pathway may also be involved. In addition, the acute inflammatory response is linked to endoplasmic reticulum (ER) stress (see Fig. 33-7), resulting from accumulation of unfolded or misfolded proteins with disruption of ER homeostasis. Hepcidin expression is induced by the transcription factor cyclic AMP response element–binding protein H (CREBH) or by the stress-inducible transcription factors CCAAT/enhancer-binding protein (C/EBP) homologous protein (CHOP) and CCAAT-enhancer-binding protein-α (C/EBPα).[3,4,8,29]

INTESTINAL IRON ABSORPTION

Because humans are unable to excrete excess iron, iron balance is physiologically maintained by the control of iron absorption in the proximal portion of the duodenum. Iron overload develops if regulation of iron balance is by passed by parenteral injections of iron or transfusion. Normally, only about 1 to 1.5 mg of iron of the 10 to 20 mg in the adult diet is absorbed to balance obligatory losses. Both nonheme iron and heme iron enter through the microvillous brush border at the apical (luminal) surface of the intestinal enterocytes (Fig. 33-8).[1] Nonheme dietary iron is predominantly ferric (Fe^{3+}) and, before absorption, is converted to ferrous (Fe^{2+}) iron either by the reducing action of other dietary constituents or by the action of brush border ferrireductases, such as membrane-associated duodenal cytochrome B (DCYTB) and likely others.[1] The ferrous iron is then absorbed through divalent metal transporter 1 (DMT1), the same ferrous iron transporter that provides an exit for iron from the endosome (see earlier). The exact means by which heme iron is absorbed are still uncertain, but when inside the enterocyte, inducible heme oxygenase 1 releases the iron from protoporphyrin, apparently into a common pathway with absorbed dietary nonheme iron.[1] In the enterocyte cytosol, the iron can be (1) retained for cellular requirements or stored in cytosolic ferritin and then lost when the enterocyte is exfoliated or (2) exported through ferroportin on the enterocyte basolateral membrane. Iron export through ferroportin requires oxidation by membrane-bound hephaestin or circulating ceruloplasmin to the ferric form for binding by plasma transferrin. Control of duodenal iron uptake is intricate, depending on both local and systemic factors that involving not only hepcidin control of ferroportin but also modulation of iron absorption through HIF-2α and H ferritin expression (see Fig. 33-8).[3] Expression of FPN1B, which lacks the iron-responsive element in its 5′ untranslated region, allows enterocytes to bypass iron regulatory protein repression of ferroportin iron export even when cells throughout the body are iron deficient.[30]

FUTURE DIRECTIONS

Remarkable progress has been made in unraveling the molecular mechanisms underlying systemic iron homeostasis, but much remains to be done. Little is known about developmental changes in the absorption, utilization, and storage of iron. Management of iron disposition within the systemic circulation needs further clarification, especially with respect to the basis for the dominant role of erythropoietic iron requirements and to the integration of intracellular and systemic regulatory elements. Control of iron balance needs more elucidation to determine the basis for individual susceptibilities both to iron deficiency and to iron overload. More insight is needed into organ-specific iron handling and into the iron biology of specific disease states. We need a better understanding of iron homeostasis in the three areas in the body that are outside systemic control: the central nervous system, the testis, and the retina. Nonetheless, a pivotal point has been reached when the advances already made will begin to yield therapeutic benefits from new approaches to biological therapy using agonists and antagonists to the components of the iron regulatory pathways summarized in this chapter.[3,8]

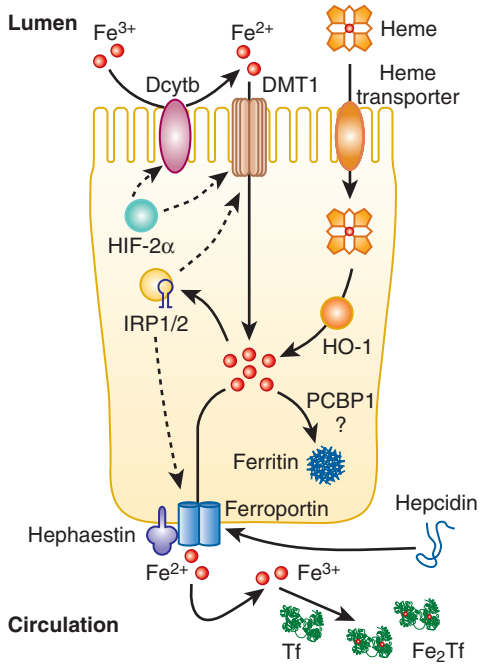

Figure 33-8 ABSORPTION OF DIETARY IRON BY THE INTESTINAL ENTEROCYTE. In the gastrointestinal lumen, dietary iron is presented to the enterocyte as heme or nonheme iron. Heme iron uptake is not well characterized, and the specific membrane transporter remains uncertain. After absorption, heme oxygenase 1 (HO-1) releases iron from heme into a common cytosolic pool. Nonheme dietary iron is predominantly ferric (Fe^{3+}) and, before absorption, is converted to ferrous (Fe^{2+}) iron either by the reducing action of other dietary constituents or by the action of brush border ferrireductases, such as membrane-associated duodenal cytochrome B (DCYTB) and likely others. Ferrous iron is then transported across the apical membrane by the divalent metal transporter 1 (DMT1) into the common cytosolic iron pool. Iron may be transported into plasma through ferroportin, regulated by hepcidin, with hephaestin or circulating ceruloplasmin acting as ferrioxidases. Cytosolic iron in excess of systemic needs may be carried to ferritin by the cytosolic iron chaperone poly (rC) binding protein 1 (PCBP1), retained and then lost when the enterocyte is shed. In addition to regulation by hepcidin, enterocyte iron absorption is modulated by hypoxia inducible factor 2α (HIF-2α), H ferritin and the iron regulatory proteins (IRP1 and 2). The enterocyte also derives iron from plasma transferrin (Tf) via the transferrin cycle (not shown). See text for details. *Fe_2Tf,* Diferric transferrin. *(Modified from Anderson GJ, Frazer DM, McLaren GD: Iron absorption and metabolism.* Curr Opin Gastroenterol *25:129, 2009.)*

CHAPTER 34

DISORDERS OF IRON HOMEOSTASIS: IRON DEFICIENCY AND OVERLOAD

Gary M. Brittenham

Iron is an essential nutrient required by every human cell. Both decreases and increases in body iron may be clinically important. If too little iron is available (iron deficiency), limitations on the synthesis of physiologically active iron-containing compounds can have harmful consequences. If too much iron accumulates (iron overload) and exceeds the body's capacity for safe transport and storage, iron toxicity may produce widespread organ damage and death. This chapter focuses on the clinical application of recent remarkable progress in understanding the molecular mechanisms underlying iron homeostasis.

Iron disorders are principally abnormalities in the amount or distribution of body iron. A fundamental advance has been the recognition that the interaction of hepcidin, the iron-regulatory hormone, with ferroportin, the cellular iron export channel, is primarily responsible for the quantity and tissue disposition of body iron. Hepcidin controls iron absorption, utilization, and storage by binding to and inducing the degradation of ferroportin, decreasing iron entry into plasma from macrophages, hepatocytes, and intestinal enterocytes (see box on Control of Iron Homeostasis by Hepcidin and Ferroportin and Chapter 33). Hepcidin expression is suppressed with iron deficiency, hypoxia, or increased erythropoietic demand but stimulated with iron overload, inflammation, or infection. Genetic and acquired disorders with a deficiency in hepcidin production or with ferroportin resistance to hepcidin action produce iron overload. Hepcidin excess from genetic causes produces iron-deficiency anemia, but acquired forms, such as those associated with infection or inflammation, result in iron sequestration and anemia.

LABORATORY EVALUATION OF IRON STATUS

Because iron disorders primarily produce quantitative abnormalities in the amount and tissue distribution of iron, laboratory evaluation of iron status relies on indicators of iron supply and storage. The principal routes of iron movement, the amounts and distribution of the major iron pools, and the sites of hepcidin control of iron entry into plasma are shown in Fig. 33-1. The continuum of changes with increased or decreased body iron content is illustrated in Fig. 34-1, showing schematically the amounts of erythroid iron and storage iron together with the division of iron stores between hepatocyte and reticuloendothelial macrophage deposits and with characteristic values for some clinically available indicators of iron status.

Body iron supply and stores can be evaluated by both direct and indirect means, but no single indicator or combination of indicators is ideal for evaluation of iron status in all clinical circumstances. As body iron content decreases from the iron-replete normal to the amounts found in iron-deficiency anemia or as it increases to the magnitudes found in the various forms of iron overload, each available measure reflects in a different manner the continuum of changes shown in Fig. 34-1. In addition, each indicator may be affected by coexisting conditions that modulate hepcidin expression, such as infection, inflammation, malignancy, ineffective erythropoiesis, hypoxemia, liver disease, and malnutrition (see box on Control of Iron Homeostasis by Hepcidin and Ferroportin and Chapter 33).

Direct Measures

The direct measures of body iron status yield quantitative, specific, and sensitive determinations of body or tissue iron stores. Quantitative phlebotomy provides a direct measure of total mobilizable storage iron. Quantitative phlebotomy is inapplicable to most anemic disorders but occasionally is useful in the diagnostic evaluation of some forms of iron overload (e.g., in patients with hereditary hemochromatosis who do not undergo liver biopsy). Bone marrow (BM) aspiration and biopsy can provide information about (1) macrophage storage iron by semiquantitative grading of marrow hemosiderin stained with Prussian blue (Fig. 34-2) or, if needed, by chemical measurement of nonheme iron; (2) iron supply to erythroid precursors by determining the proportion and morphology of marrow sideroblasts (i.e., normoblasts with visible aggregates of iron in the cytoplasm); and (3) general morphologic features of hematopoiesis. BM aspiration and biopsy are useful in studies of iron deficiency but of limited applicability in the evaluation of iron overload because no information about the extent of hepatocyte iron deposition is provided. In the evaluation of iron overload, liver biopsy is the best direct test for assessing iron deposition, permitting quantitative measurement of the nonheme iron concentration and histochemical examination of the pattern of iron accumulation in hepatocytes and macrophages (Kupffer cells).

Direct methods for assessing iron status have the disadvantages of being invasive procedures, with their attendant discomfort, lack of acceptability to patients, and, in the case of liver biopsy, risk. A variety of noninvasive means of measuring tissue iron stores has been developed and applied in clinical studies, including determination of hepatic magnetic susceptibility, computed tomography, and magnetic resonance imaging (MRI). MRI, the most widely available method, can provide information about iron deposition in the liver, spleen, heart, pancreas, and brain.[7] When available as appropriately calibrated and validated techniques, these noninvasive methods are helpful in the diagnosis and management of iron overload but lack the accuracy required to detect iron deficiency.

Indirect Measures

Indirect measures of body iron status have the advantages of ease and convenience but all are subject to extraneous influences and lack specificity, sensitivity, or both. When used to estimate body iron stores, all of the available indirect measures are influenced not only by total body iron stores but also by the effects of acute or chronic changes in plasma hepcidin (see box on Control of Iron Homeostasis by Hepcidin and Ferroportin). Assays for urinary and plasma hepcidin are not yet generally available but are under development and likely to be helpful in the clinical evaluation of patients with disorders of iron homeostasis.[8]

Measurement of the plasma ferritin concentration provides the most useful indirect estimate of body iron stores.[9] The small amounts of ferritin secreted into the circulation can be measured by immunoassay and have a logarithmic relationship to body iron stores in healthy persons. In the absence of complicating factors, plasma ferritin concentrations decrease with depletion of storage iron and

Control of Iron Homeostasis by Hepcidin and Ferroportin

Hepcidin functions as the chief controller of body iron supply and storage by interacting with ferroportin, a transmembrane protein that is the only known iron exporter in humans[1-3] (see Chapter 33). Hepcidin binds to ferroportin, inducing its internalization and degradation, thereby inhibiting iron efflux from the principal sources of plasma iron—macrophages, duodenal enterocytes, and hepatocytes (see Fig. 33-1). Under physiologic conditions, hepatic hepcidin production coordinates body iron supply with iron need.[1-3] If body iron stores expand, hepatic hepcidin production increases. Increments in plasma hepcidin reduce the amount of ferroportin in cell membranes, causing a prompt fall in plasma iron concentration by decreasing macrophage release of iron derived from senescent red blood cells, diminishing delivery of iron from enterocytes absorbing dietary iron, and inhibiting release of iron stored in hepatocytes. Conversely, if body iron stores diminish, hepatic hepcidin production decreases. Decrements in plasma hepcidin concentration increase the amount of ferroportin, producing a rise in plasma iron concentration as a consequence of enhanced delivery from macrophages, increased dietary iron absorption from enterocytes, and mobilization of storage iron from hepatocytes. In addition to the effects of body iron stores, hepcidin production is stimulated by infection, inflammation, or malignancy and inhibited by hypoxemia or increased erythropoietic demand. The influence of infection and inflammation on hepcidin and ferroportin expression link iron sequestration to host defense,[2,4] and the interaction with erythropoiesis connects iron supply to red blood cell production.[2,5] Depending on clinical circumstances, the effects of inflammation or erythropoiesis on hepatic hepcidin synthesis may predominate over those of body iron stores. Liver disease and malnutrition may also impair hepcidin expression. Although hepcidin is the central regulator of iron homeostasis, hypoxia inducible factor 2-α (HIF2-α) and H-ferritin modulate intestinal iron absorption.[6]

increase with storage iron accumulation (see box on Plasma Ferritin Concentrations). Measurement of the plasma transferrin receptor concentration provides a useful means of detecting tissue iron deficiency.[10] A majority of plasma transferrin receptors are derived from the erythroid marrow, and their concentration is determined primarily by erythroid marrow activity. Whereas decreased levels of circulating soluble transferrin receptor are found in patients with erythroid hypoplasia (aplastic anemia, chronic renal failure), increased levels are present in patients with erythroid hyperplasia (thalassemia major, sickle cell anemia, anemia with ineffective erythropoiesis, chronic hemolytic anemia). Iron deficiency also increases soluble transferrin

Plasma Ferritin Concentrations

Plasma ferritin concentrations are helpful in the detection of both iron deficiency and iron overload.[9] Plasma ferritin concentrations decline with storage iron depletion; a plasma ferritin concentration less than 12 mg/L is virtually diagnostic of absence of iron stores. The only known conditions that may lower the plasma ferritin concentration independently of a decrease in iron stores are hypothyroidism and ascorbate deficiency, but these conditions only rarely cause problems in clinical interpretation. Increased plasma ferritin concentrations may indicate increased storage iron, but a number of disorders may increase the plasma ferritin level independently of the body iron store. Plasma ferritin is an acute-phase reactant with increased ferritin synthesis a nonspecific response that is part of the general pattern of the systemic effects of inflammation.[4,9] Thus, fever, acute infections, rheumatoid arthritis, and other chronic inflammatory disorders elevate the plasma ferritin concentration. Both acute and chronic damage to the liver, as well as to other ferritin-rich tissues, may increase plasma ferritin concentration through an inflammatory process or by releasing tissue ferritins from damaged parenchymal cells.[9]

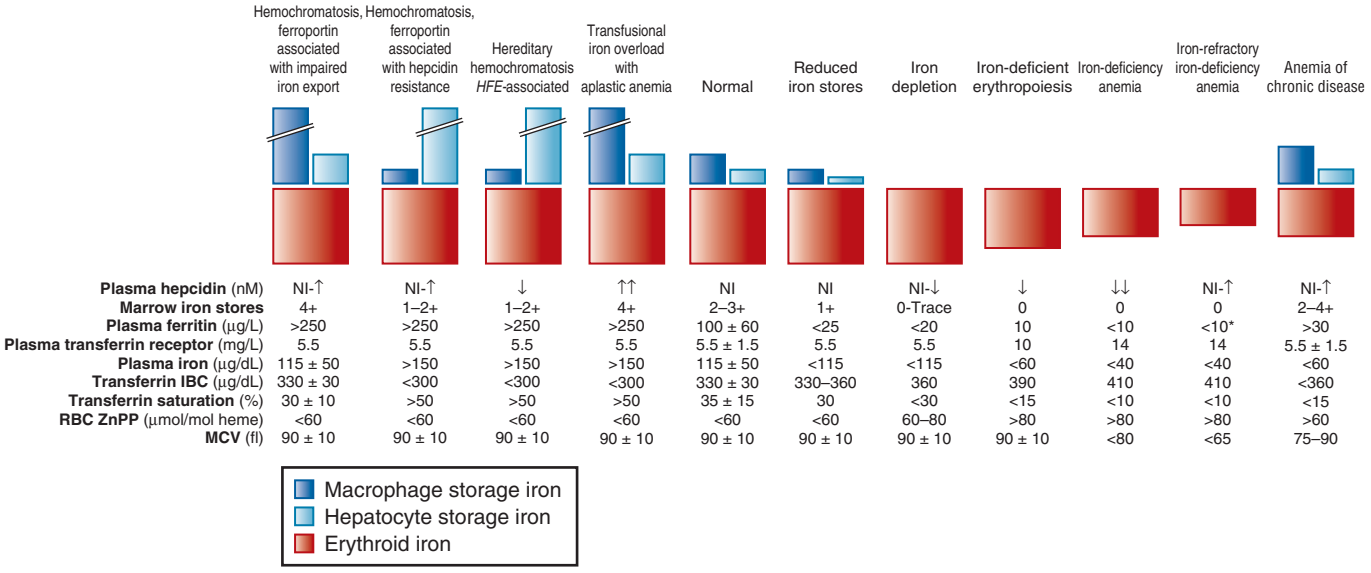

Figure 34-1 CONTINUUM OF CHANGES IN THE AMOUNTS OF ERYTHROID IRON AND OF HEPATOCYTE AND RETICULOENDOTHELIAL MACROPHAGE STORAGE IRON IN THE PRESENCE OF INCREASED OR DECREASED BODY IRON CONTENT. Characteristic values for some clinically available indicators of iron status are shown. In iron overload, the *diagonal lines* are intended to illustrate increases in excess storage iron from the normal range of 1 g or less to as much as 40 to 50 g. *, Plasma ferritin may be normal or increased after administration of parenteral iron; *HFE,* gene for the hemochromatosis protein, HFE; *IBC,* iron-binding capacity; *MCV,* mean corpuscular volume; *RBC,* red blood cell; *ZnPP,* zinc protoporphyrin.

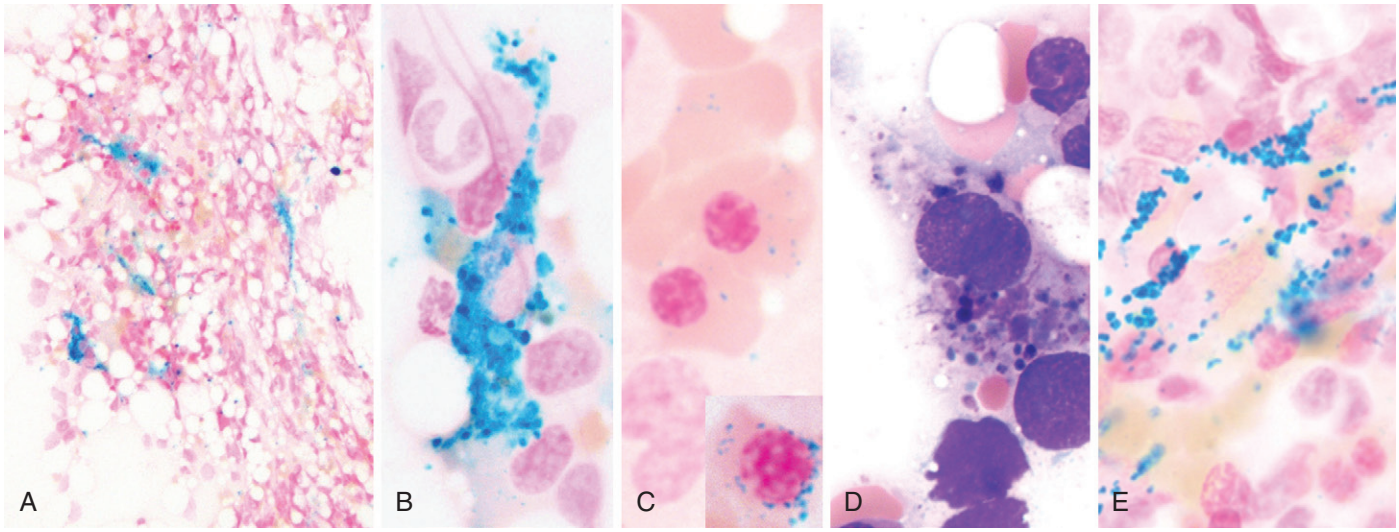

Figure 34-2 ASSESSMENT OF IRON STORES ON A BONE MARROW ASPIRATE. Iron stores are usually assessed on the aspirate as opposed to the biopsy because the decalcification procedure required for processing the biopsy leaches out the iron and can lead to a false conclusion of absent stores. On the aspirate, a Prussian blue stain is usually used to evaluate iron. This can demonstrate iron stores (blue reaction product), particularly in the cytoplasm of macrophages and histiocytes **(A** and **B)**. Iron can also be seen in the cytoplasm of some nucleated red blood cells (tiny blue cytoplasmic specks), which would allow these cells to be designated *sideroblasts* **(C).** These are in contrast to red blood cell precursors with abnormal iron accumulation around the nucleus, or "ring sideroblasts" (**C,** *insert*). Hemosiderin containing iron can be seen on the Wright-stained aspirate smears as a dark brown or black pigment in histiocytes **(D),** but generally an iron stain is needed to confirm the presence of iron stores. When parenteral iron therapy is administered, the marrow aspirate can sometimes show coarse iron deposits frequently in long streaks **(E).** This is most likely iron in endothelial cells; it does not necessarily indicate marrow iron is present.

receptor concentrations. The plasma transferrin receptor concentration reflects the total body mass of tissue receptor; thus, in the absence of other conditions causing erythroid hyperplasia, an increase in plasma transferrin receptor concentration provides a sensitive, quantitative measure of tissue iron deficiency.[10] In particular, measurement of plasma transferrin receptor concentration may help differentiate between the anemia of iron deficiency and the anemia associated with chronic inflammatory disorders. Although the plasma ferritin concentration may be disproportionately elevated in relation to iron stores in patients with inflammation or liver disease, the plasma transferrin receptor concentration seems to be less affected by these disorders and to provide a more reliable laboratory indicator of iron deficiency.[10]

The erythrocyte zinc protoporphyrin provides an indicator of iron supply to erythroid precursors. In heme biosynthesis, the final reaction is chelation of a ferrous ion by protoporphyrin IX. If no iron is available, zinc is chelated instead to form zinc protoporphyrin. Because zinc protoporphyrin formed during development persists throughout the lifespan of the red blood cell (RBC), the blood concentration changes only as new cells are formed and old cells are destroyed, providing a retrospective view of iron supply over the preceding several weeks. Levels also are increased in many sideroblastic anemias and especially with chronic lead poisoning. The test is of no value in detecting iron overload.

Measurements of the proportion of hypochromic circulating RBCs and the hemoglobin content of reticulocytes (CHr) are possible with some hematology analyzers and offer new means of detecting restriction of the iron supply for erythropoiesis.[11] Measurement of urinary iron excretion with chelating agents, usually either deferoxamine or diethylenetriamine pentaacetic acid, offers another means of assessing body iron stores. This test is not helpful for detecting iron deficiency because of the overlap between values in persons with normal and those with decreased iron stores; it is used occasionally for the evaluation of iron overload.

Examination of peripheral blood by measurements of hemoglobin concentration, hematocrit, RBC indices, RBC volume distribution, and reticulocyte count and by inspection of erythrocyte morphology reveals abnormalities only after depletion of iron stores restricts the availability of iron for erythropoiesis. The changes are not specific for iron deficiency and may be found in other conditions with defective hemoglobin synthesis, such as thalassemia, infection, inflammation, liver disease, and malignancy. Iron overload does not produce any diagnostic abnormalities in the peripheral blood.

IRON DEFICIENCY

Iron deficiency is a decrease in the amount of body iron resulting from a sustained increase in iron requirements over iron supply. The continuum of decreased body iron is shown in Fig. 34-1. Three successive stages of iron lack can be distinguished. A decrement in storage iron without a decline in the level of functional iron compounds is termed *iron depletion* (see Fig. 34-1). After iron stores are exhausted, lack of iron limits the production of hemoglobin and other metabolically active compounds that require iron as a constituent or cofactor. Iron-deficient erythropoiesis (see Fig. 34-1) develops, although the effect on hemoglobin production may be insufficient to be detected by the standards used to differentiate normal from anemic states. Further diminution in the body iron produces frank iron-deficiency anemia (see Fig. 34-1). Iron regulation of erythroid differentiation coordinates the rate of erythropoiesis with iron availability. Iron deficiency reduces the responsiveness of erythroid progenitors to erythropoietin, apparently through an iron–aconitase–isocitrate pathway.[5,12] With a lack of iron, decreased erythroid utilization for RBC production helps preserve the supply of iron for vital functions in other tissues.

Epidemiology

Iron deficiency is the most common cause of anemia in the United States and worldwide. In the United States, adequacy of bioavailable iron in the diet, together with food fortification and the widespread use of iron supplements, has reduced the overall prevalence and severity of iron deficiency, but iron nutrition remains a problem in some subpopulations, especially toddlers, adolescent girls, women of childbearing age, and some minority groups. Without iron supplementation, most women will become iron deficient during pregnancy. Globally, 30% to 70% of the populations in developing countries are

iron deficient, with the highest prevalence among persons who have diets low in bioavailable iron, who have chronic gastrointestinal blood loss as a result of helminthic infection, or both.

Etiology and Pathogenesis

The foremost task in the evaluation of patients with iron deficiency is identifying and treating the underlying cause of the imbalance between iron requirements and supply that is responsible for the lack of iron (Table 34-1). Overall, the iron requirement for an individual includes not only the iron needed to replenish physiologic losses and meet the demands of growth and pregnancy but also any additional amounts needed to replace pathologic losses. Physiologic iron losses generally are restricted to the small amounts of iron contained in the urine, bile, and sweat; shedding of iron-containing cells from the intestine, urinary tract, and skin; occult gastrointestinal blood loss; and, in women, uterine losses during menstruation and pregnancy. In normal men, the daily basal iron loss is slightly less than 1.0 mg/day. In normal menstruating women, the daily basal iron loss is approximately 1.5 mg/day. The median total iron loss with pregnancy is approximately 500 mg, or almost 2 mg/day over the 280 days of gestation.

The most common pathologic cause of increased iron requirements leading to iron deficiency is blood loss.[13] In men and postmenopausal women, iron deficiency almost inevitably signifies gastrointestinal blood loss. Within the gastrointestinal tract, any hemorrhagic lesion may result in blood loss, and the responsible lesion may be asymptomatic.[13] Iron deficiency often is the first sign of an occult gastrointestinal malignancy or other unrecognized conditions such as coeliac disease, or autoimmune, atrophic, or *Helicobacter pylori* gastritis. Chronic ingestion of drugs such as alcohol, salicylates, steroids, and nonsteroidal antiinflammatory drugs may cause or contribute to blood loss. Worldwide, the most frequent cause of gastrointestinal blood loss is hookworm infection, but other helminthic infections, such as *Schistosoma mansoni* and *Schistosoma japonicum,* and severe *Trichuris trichiura* infection also may be responsible.

In women of childbearing age, genitourinary blood loss with menstruation adds to iron requirements.[13] Other less frequent causes of genitourinary bleeding may be involved, including chronic hemoglobinuria and hemosiderinuria resulting from paroxysmal nocturnal hemoglobinuria or from chronic intravascular hemolysis. Uncommonly, respiratory tract blood loss resulting from chronic recurrent hemoptysis of any cause produces iron deficiency.

In infants, children, and adolescents, the need for iron for growth may exceed the supply available from diet and stores.[14] Premature infants, who have a lower birth weight and a more rapid postnatal rate of growth, are at high risk for iron deficiency unless given iron supplements. With rapid growth during the first year of life, the body weights of term infants normally triple, and iron requirements are at high levels. Iron requirements decline as growth slows during the second year of life and into childhood but rise again with the adolescent growth spurt.

Without supplemental iron, pregnancy entails the net loss of the equivalent of 1200 to 1500 mL of blood.[13] After delivery, resumption of menstruation usually is delayed for months. If the infant is breastfed, lactation necessitates an intake of about 0.5 to 1.0 mg of iron daily.

In some instances, an insufficient supply of iron may contribute to the development of iron deficiency. In infants or in women who have experienced heavy menstrual losses or multiple pregnancies, the risk of iron deficiency may be further increased by diets with insufficient amounts of bioavailable iron, such as those with little or no heme iron and with small amounts of enhancers or large amounts of inhibitors of nonheme iron absorption. For older children, men, and postmenopausal women, the restricted availability of dietary iron is almost never the sole explanation for iron deficiency, and other causes, especially blood loss, must be considered.

Impaired absorption of iron in itself infrequently is the sole source of iron deficiency.[13] Nonetheless, in patients in whom evaluation fails to identify a source of blood loss, as well as in those unresponsive to oral iron therapy, coeliac disease, autoimmune, atrophic, or *H. pylori* gastritis may be responsible. Iron deficiency frequently complicates gastric surgery, such as partial or total gastric resection or gastroenterostomy for bypass of the duodenum.

Increased iron requirements and an inadequate supply of iron often work in concert to produce iron deficiency. Infants fed cow's milk receive a diet that not only contains small amounts of iron of low bioavailability but also increases iron losses by causing gastrointestinal bleeding.[14] Patients with ulcer disease and increased gastrointestinal blood loss may habitually take antacids or proton pump inhibitors, which diminish dietary iron absorption.[13]

An uncommon heritable cause of iron deficiency is iron-refractory iron-deficiency anemia (IRIDA), an autosomal recessive disorder with severe iron-deficiency anemia and increased concentrations of plasma hepcidin.[15] The anemia is unresponsive to orally administered iron and incompletely responsive to parenteral iron. Mutations in *TMPRSS6,* a gene that normally inhibits hepcidin production, are responsible (see Chapter 33).

Clinical Presentation

Patients with iron deficiency may present with (1) no signs or symptoms, coming to medical attention only because of abnormalities noted on laboratory tests; (2) features of the underlying disorder responsible for the development of iron deficiency; (3) manifestations common to all anemias; or (4) one or more of the few signs and symptoms considered highly specific for iron deficiency, namely, pagophagia, koilonychia, and blue sclerae. In addition, a high prevalence of iron deficiency with or without anemia has been reported among patients with the restless legs syndrome, a neurologic disorder characterized by a distressing need or urge to move the legs (akathisia).[16]

An uncomplicated depletion of storage iron generally is not associated with signs or symptoms, although patients without iron reserves will not respond as rapidly to an increased need for iron resulting from blood loss, growth, or pregnancy. Iron-deficiency anemia produces the signs and symptoms common to all anemias, which are pallor, palpitations, tinnitus, headache, irritability, weakness, dizziness, easy fatigability, and other vague and nonspecific complaints. The prominence of these signs depends on the degree and rate of development of the anemia. With greater severity, anemia becomes increasingly debilitating as work capacity and tolerance of physical exertion are restricted and eventually can produce cardiorespiratory failure and even death.

Iron deficiency may produce clinical manifestations independent of anemia. Epithelial tissues have high iron requirements because of rapid rates of growth and turnover and thus are affected in many patients with chronic iron deficiency. Glossitis, angular stomatitis,

postcricoid esophageal web or stricture (which may become malignant), and gastric atrophy may develop. Pagophagia, a variant of pica in which ice is the substance obsessively consumed, is a behavioral abnormality that is considered to be a highly specific symptom of iron deficiency, resolving within a few days to 2 weeks after beginning iron therapy. Iron deficiency has other nonhematologic consequences, including impaired immunity and resistance to infection, diminished exercise tolerance and work performance, and a variety of behavioral and neuropsychologic abnormalities. In patients with iron deficiency and heart failure, clinical trials have provided evidence that treatment with intravenous iron improves outcomes.[17]

Laboratory Evaluation

A characteristic sequence of changes in the clinically useful indications of iron status occurs as body iron decreases from the iron-replete normal to the levels found in iron-deficiency anemia. This sequence is illustrated in Fig. 34-1. The patterns shown develop in the absence of complicating factors that increase plasma hepcidin, such as infection, inflammation, liver disease, malignancy, or other disorders (see box on Iron Deficiency and Coexisting Disorders). Initially, as a result of any of the causes listed in Table 34-1, iron requirements exceed the available supply of iron. Iron is mobilized from body stores, and iron absorption is increased. If the amounts of iron available from body reserves and absorption are inadequate, storage iron depletion follows. Exhaustion of iron reserves then results in an inadequate supply of iron to the developing erythroid cell, and iron-deficient erythropoiesis commences. As hemoglobin production becomes restricted, frank iron-deficiency anemia develops (see box on Plasma Iron Concentration and Transferrin Saturation).

Chronic, long-standing iron-deficiency anemia may produce severe microcytosis and hypochromia, with very pale, distorted RBCs and dramatic reductions in the mean corpuscular volume and mean corpuscular hemoglobin (Fig. 34-3). In contrast, some patients with mild iron-deficiency anemia may have erythrocyte morphology and indices indistinguishable from values found in normal, iron-replete individuals. Nonetheless, laboratory evaluation of uncomplicated iron deficiency in otherwise healthy persons usually is not difficult, and the characteristic patterns of indicators of body iron status shown in Fig. 34-1 typically are diagnostic. Diagnostically, early or mild iron deficiency must be considered in the workup of normocytic as well as microcytic anemia.

Iron Deficiency and Coexisting Disorders

Detection of iron deficiency in the presence of chronic infectious, inflammatory, or malignant disorders that increase plasma hepcidin is more problematic than in the absence of such disorders.[4] Even if iron lack contributes to the anemia of chronic disorders, the increase in plasma hepcidin will lead to a fall in the transferrin concentration (or total iron-binding capacity) and an increase in the plasma ferritin concentration.[9,18] Because the serum transferrin receptor concentration is less affected by inflammation, its measurement usually can determine whether iron stores are absent.[10] If uncertainty remains, BM examination is definitive. If iron deficiency is present, iron stores are absent; if the anemia of chronic disorders alone is responsible, iron stores are present and typically increased (see Figure 34-1).

Plasma Iron Concentration and Transferrin Saturation

Plasma iron concentration and transferrin saturation, which equals the ratio of plasma iron to total iron-binding capacity, provide a measure of current iron supply to tissues. After storage iron is depleted, the serum iron concentration falls; a transferrin saturation less than 16% often is used as the criterion for iron-deficient erythropoiesis.[13] In contrast, plasma iron concentration and transferrin saturation are not reliably elevated with increased iron stores within macrophages, as occurs initially with transfusional iron overload, although the transferrin saturation may increase with parenchymal iron loading. Interpretation of the transferrin saturation is complicated by substantial circadian fluctuations in plasma iron concentration with day-to-day variations of 30% or greater. Furthermore, the plasma iron concentration is lowered by ascorbate deficiency and by conditions that increase plasma hepcidin, such as infection, inflammation, malignancy.[4] Plasma iron is raised by iron ingestion and by conditions that decrease plasma hepcidin, such as hypoxemia, erythroid hyperplasia with ineffective erythropoiesis, and liver disease.[3]

Differential Diagnosis

Iron deficiency is the only microcytic hypochromic disorder in which mobilizable iron stores are absent; in all other disorders, storage iron is normal or increased (Table 34-2). In patients with the genetic disorder of iron-refractory iron-deficiency anemia, iron stores may be normal or increased after treatment with parenteral iron.[15] Difficulties in the evaluation of microcytic hypochromic disorders usually arise when direct assessment of BM iron is unavailable and the diagnosis depends on indirect indicators of iron status (see boxes on Iron Deficiency and Coexisting Disorders and Therapeutic Trial of Iron).

Specific entities to be considered in the differential diagnosis of hypochromic microcytic disorders are listed in Table 34-2; in all of these disorders, body iron stores are normal or increased. The anemia of chronic disease (see Chapter 35) is the most common cause of anemia in hospitalized patients and generally is mild to moderate, typically developing over several weeks in patients with chronic infectious, inflammatory, or malignant disorders. In patients treated with erythropoiesis-stimulating agents for the anemia of chronic renal disease or other disorders, the increased iron requirements of the erythroid BM cannot be met by iron mobilization from replete stores, resulting in iron-restricted erythropoiesis.[19] This state, sometimes labeled "functional iron deficiency" despite the presence of storage iron, is a form of iron-restricted erythropoiesis resulting from stimulated erythropoietic demand for iron.[18] Uncommonly, a similar pattern can result from endogenous increases in erythropoietin owing to anemia, hypoxemia, and other conditions. The reticulocyte hemoglobin content (CHr) may be the earliest indicator that stimulated erythropoietic demand for iron exceeds the available supply.[11]

Therapeutic Trial of Iron

The diagnosis of iron deficiency often is confirmed by the outcome of a therapeutic trial of iron. A specific orderly response to, and only to, treatment with iron constitutes the final definitive proof that a lack of iron is the cause of anemia. The unequivocal diagnostic response consists of (1) a reticulocytosis, which begins approximately 3 to 5 days after adequate iron therapy is instituted, reaches a maximum on days 8 to 10, and then declines; and (2) a significant increase in hemoglobin concentration, which should begin shortly after the reticulocyte peak, is invariably present by 3 weeks after iron therapy is begun, and persists until the hemoglobin concentration is restored to normal. The result of a therapeutic trial of iron must be evaluated for possible confounding factors, such as poor compliance with iron therapy; malabsorption of therapeutic iron; continuing blood loss; and the effects of coexisting conditions, especially infectious, inflammatory, or malignant disorders. The therapeutic trial merely aids in establishing the presence of iron deficiency. The search for underlying causes of iron deficiency must continue despite a positive response to iron therapy.

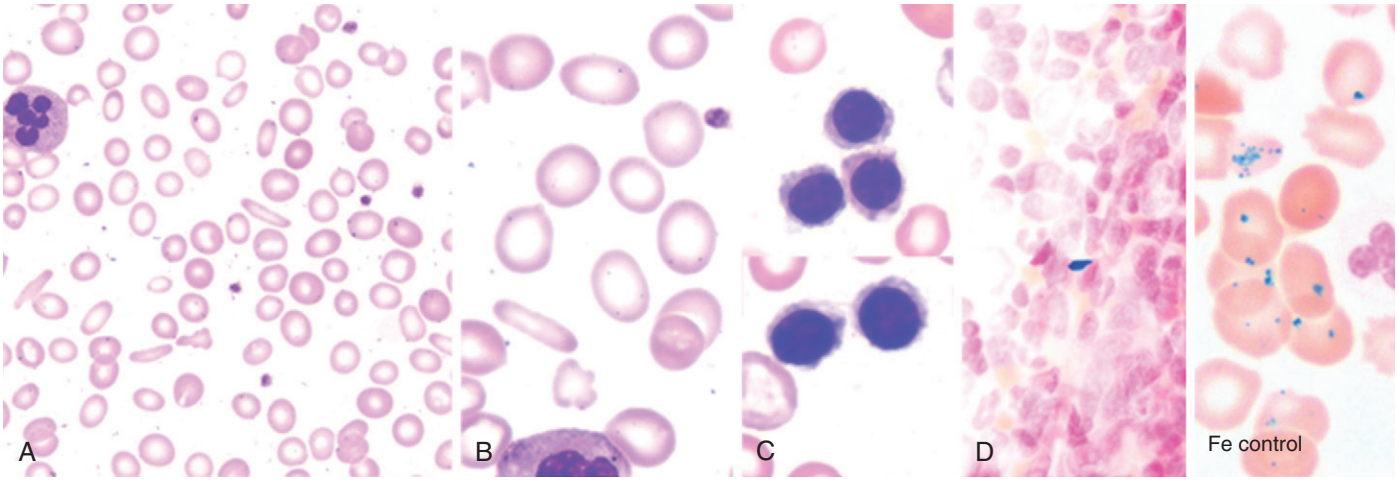

Figure 34-3 IRON-DEFICIENCY ANEMIA. Peripheral blood smear **(A** and **B)**, bone marrow (BM) aspirate **(C),** and Prussian blue stain of BM aspirate **(D)** with control from a 16-year-old girl with hemoglobin 6.7 g/dL, hematocrit 22.6%, and mean corpuscular volume 59.2 fL. Peripheral smear shows hypochromic microcytic red blood cells **(A),** with widening of the central pallor and "pencil" cells **(B).** Polychromatophilic erythroid precursors in the aspirated specimen have scanty cytoplasm that is irregular and vacuolated **(C).** The Prussian blue–stained aspirate shows no iron stores in multiple spicules **(D).** Care must be taken not to overinterpret positive staining debris on top of cells *(center)*. Lack of staining on the BM biopsy sample can be misleading because the decalcification process is known to "leach out" iron. An appropriate control should be similar to the patient material. Peripheral blood smears made from a patient with increased iron-containing Pappenheimer bodies and fixed with 100% methanol can serve as an easily accessible control.

Table 34-2 Differential Diagnosis of Microcytic Hypochromic Anemia

Decreased Body Iron Stores
Iron-deficiency anemia
Normal or Increased Body Iron Stores
Anemia of chronic disease
Defective absorption, transport, or use of iron
Iron-refractory, iron-deficiency anemia after parenteral iron
Atransferrinemia
Aceruloplasminemia
Divalent metal transporter 1 (DMT1 or SLC11A2) deficiency
Ferroportin-associated hemochromatosis with impaired iron export (type 4A)
Heme oxygenase 1 deficiency
Disorders of globin synthesis
Thalassemia
Other microcytic hemoglobinopathies
Disorders of heme synthesis: sideroblastic anemias
Hereditary
Acquired

Oral Iron Therapy

Oral iron therapy should begin with a ferrous iron salt[13] taken separately from meals in three or four divided doses and supplying a daily total of 150 to 200 mg of elemental iron in adults or 3 mg of iron per kilogram of body weight in children. Simple ferrous preparations are the best absorbed and least expensive. Ferrous sulfate is the most widely used, either as tablets containing 60 to 70 mg of iron for adults or as a liquid preparation for children. Administration between meals maximizes absorption. In patients with a hemoglobin concentration less than 10 g/dL, this regimen initially provides approximately 40 to 60 mg of iron daily for erythropoiesis, permitting RBC production to increase to two to four times normal and the hemoglobin concentration to rise by approximately 0.2 g/dL/day. An increase in the hemoglobin concentration of at least 2 g/dL after 3 weeks of therapy generally is used as the criterion for an adequate therapeutic response. For milder anemia, a single daily dose of approximately 60 mg of iron per day may be adequate. After the anemia has been fully corrected, oral iron should be continued to replace storage iron, either empirically for an additional 4 to 6 months or until the plasma ferritin concentration exceeds approximately 50 μg/L.

Microcytic hypochromic anemias resulting from disorders of heme synthesis (sideroblastic anemias, congenital and acquired) and disorders of globin synthesis (thalassemias, microcytic hemoglobinopathies) are discussed in Chapters 36 and 38, respectively. Other rare congenital or acquired defects with microcytic hypochromic anemias[6] include atransferrinemia, aceruloplasminemia, divalent metal transporter 1 (DMT1 or SLC11A2) deficiency, some forms of ferroportin disease, heme oxygenase 1 deficiency (mutations in *HMOX1*, encoding heme oxygenase 1), several inherited sideroblastic anemias,[12,20] and a variety of other uncommon disorders.

Therapy

The goal of therapy for iron-deficiency anemia is to supply sufficient iron to repair the hemoglobin deficit and replenish storage iron. Generally, iron therapy for iron deficiency can be deferred until the underlying cause of the lack of iron has been identified. Oral iron is the treatment of choice for most patients because of its effectiveness, safety, and economy and should always be given preference over parenteral iron for initial treatment[13] (see box on Oral Iron Therapy). The risk of local and systemic adverse reactions restricts the use of parenteral iron to patients who are unable to absorb or tolerate adequate amounts of oral iron.[21,22] Rarely, RBC transfusions are needed to prevent cardiac or cerebral ischemia in patients with severe anemia or to support patients whose chronic rate of iron loss exceeds the rate of replacement possible with parenteral therapy.

Most patients are able to tolerate oral iron therapy without difficulty, but 10% to 20% may have symptoms attributable to iron. The most common side effects are gastrointestinal.[13] Decreasing the amount of iron in each dose usually is effective in controlling side effects, but if symptoms persist, a reduction in frequency to a single daily dose may be helpful. Costly iron preparations with other additives, polysaccharide–iron complexes, or enteric coatings or in sustained-release forms do not appear to offer any advantages that

Parenteral Iron Therapy

Five parenteral iron preparations are approved for use in the United States: higher and lower molecular-weight iron dextran, sodium ferric gluconate complex, iron sucrose, and ferumoxytol.[21] Each has been widely used, often in hemodialysis patients receiving recombinant human erythropoietin, but neither prospective, randomized controlled comparisons among the five agents nor long-term safety studies have been done. Although infrequent, immediate life-threatening anaphylactic reactions constitute the most serious risk associated with use of either intramuscular or intravenous iron preparations, may have a fatal outcome, and can occur with all five parenteral iron preparations.[22] Delayed but severe serum sickness–like reactions may also develop, with fever, urticaria, adenopathy, myalgias, and arthralgias.

cannot be achieved by simply reducing the dose of plain ferrous salts. Administering iron with food and decreasing the dose will diminish the amount of iron absorbed daily and thereby prolong the period of treatment, but haste in the correction of iron deficiency is rarely needed.

Parenteral iron therapy (see box on Parenteral Iron Therapy), with the risk of adverse reactions, should be reserved for the exceptional patient who (1) remains intolerant of oral iron despite repeated modifications in dosage regimen; (2) has iron needs that cannot be met by oral therapy because of either chronic uncontrollable bleeding or other sources of blood loss, such as hemodialysis, or a coexisting chronic inflammatory state; or (3) malabsorbs iron.[21,22]

Prognosis

The prognosis for iron deficiency itself is excellent, and the response to either oral or parenteral iron also is excellent.[13] Frequently, both clinical and subjective indications of constitutional improvement are seen within the first few days of treatment, with the patient reporting an enhanced sense of well-being and increased vigor and appetite. Pica may resolve, and soreness and burning of the mouth abate. Mild reticulocytosis begins within 3 to 5 days, is maximal by days 8 to 10, and then declines. The hemoglobin concentration begins to increase after the first week and usually returns to normal within 6 weeks. Complete recovery from microcytosis may take up to 4 months. With oral iron dosage totalling 200 mg/day or less, the plasma ferritin concentration usually remains less than 12 μg/dL until the anemia is corrected and then gradually rises as storage iron is replaced over the next several months. Although epithelial abnormalities begin to improve promptly with treatment, resolution of glossitis and koilonychia may take several months. The overall prognosis depends on the underlying disorder responsible for the iron deficiency.

Failure to obtain a complete and characteristic response to iron therapy necessitates a review of findings and reevaluation of the patient. A common problem is an incorrect diagnosis, with the anemia of chronic disease mistaken for the anemia of iron deficiency. Coexisting conditions, such as other nutritional deficiencies; hepatic or renal disease; or infectious, inflammatory, or malignant disorders, may impede recovery. Occult blood loss may be responsible for an incomplete response. With oral iron therapy, the adequacy of the form and dose of iron used should be reconsidered; compliance with the treatment regimen reviewed; and, finally, the possibility of malabsorption considered.

IRON OVERLOAD

Iron overload is an increase in the amount of body iron resulting from a sustained expansion of iron supply beyond iron requirements. Because requirements are limited and humans lack a physiologic means of excreting excess iron, any persistent increase in iron influx may eventually result in iron overload. The continuum of increased body iron is shown in Fig. 34-1. Whatever the source and the sites of excess iron deposition, when the accumulation overwhelms the cellular capacity for safe storage, potentially lethal tissue damage is the result. The toxic manifestations of iron overload vary with the precise pathogenic defect responsible but are dependent on the amount of excess iron, rate of iron accumulation, cellular pattern of deposition, and presence of complicating factors such as hepatitis or drug or alcohol use.

Epidemiology

The most common form of iron overload in the United States is a genetically determined disorder, the homozygous state for hereditary hemochromatosis, which occurs in approximately 4 to 5 of every 1000 persons of northern European descent.[23-25] In the United States, other forms of iron overload are less frequent but affect thousands of patients with iron-loading or chronically transfused anemias, such as thalassemia major, sickle cell disease, and acquired refractory anemias.[26] Globally, hereditary hemochromatosis is the most common genetic disorder in populations of northern European ancestry.[23-25] Thalassemia major and other iron-loading anemias are important public health problems in countries bordering the Mediterranean and in an area extending from southwest Asia and the Indian subcontinent to southeast Asia.[26] Dietary iron overload resulting from intake of iron in brewed beverages is a common problem affecting many populations in sub-Saharan Africa and may have a genetic component.[24] Other inherited types of systemic iron overload, the various forms of perinatal iron overload, and the syndromes associated with focal sequestration of iron are uncommon or rare disorders.

Genetic Aspects

The varieties of iron overload known to be genetically determined are listed in Table 34-3, and their cardinal features are summarized in Table 34-4. The known forms of hereditary iron overload all involve defects in the interaction of hepcidin and ferroportin (see box on Control of Iron Homeostasis by Hepcidin and Ferroportin and Chapter 33). The autosomal recessive disorders have in common an inappropriately low hepatic hepcidin production that leads to parenchymal iron overload.[1,23,25] *HFE*-associated and transferrin receptor 2–associated hereditary hemochromatosis and hemojuvelin- and hepcidin-associated juvenile hemochromatosis are the consequence, respectively, of mutations in regulatory genes controlling hepcidin expression *(HFE, TFR2, HJV)* and in the structural gene for hepcidin *(HAMP)*. Hepcidin production is also suppressed in three other rare autosomal recessive disorders with distinctive syndromes of iron overload: DMT1-associated hemochromatosis, atransferrinemia, and aceruloplasminemia.[1,23,25] The autosomal dominant disorders have in common mutations in the gene for ferroportin (FPN).[1,23,25] In general, these mutations either (1) interfere with iron export, resulting in reticuloendothelial macrophage iron accumulations with only minor clinical manifestations; or (2) produce resistance to the action of hepcidin, resulting in parenchymal iron loading resembling that in the autosomal recessive forms of hereditary iron overload.

Several of the acquired forms of iron overload involve disorders with a genetic origin or component. The genetically determined iron-loading anemias include the inherited sideroblastic anemias[12,20] (see Chapter 36), some of the hereditary disorders of globin synthesis (see Chapter 38), and some chronic hemolytic anemias (see Chapters 41 to 45). Similarly, some forms of chronic liver disease and porphyria cutanea tarda (see Chapter 36) are inherited disorders. African dietary iron overload[24] and, possibly, susceptibility to iron accumulation with prolonged medicinal iron ingestion may have genetic components. Many of the disorders requiring chronic RBC transfusion are

*May have a genetic component.

hereditary, including thalassemia major (see Chapter 38), sickle cell disease (see Chapters 39 and 40), and other chronic refractory anemias. Although the exact etiology of some of these conditions is unknown, subsets of the disorders leading to perinatal iron overload or focal sequestration of iron have an established genetic basis.

Etiology and Pathogenesis

Iron overload is caused by conditions that alter or bypass the normal control of body iron content by regulation of intestinal iron absorption. The known forms of hereditary iron overload (see Table 34-3) have a common pathogenic origin in genetically determined abnormalities in the interaction of hepcidin and ferroportin that lead to excessive intestinal iron absorption, resulting in body iron accumulation. The rate, distribution, and harmful effects of tissue iron loading depend on the specific abnormality in the interaction between hepcidin and ferroportin produced by each mutation.

The mechanisms of toxicity in vulnerable iron-loaded cells seem to involve expansion of the pool of cytosolic iron followed by iron-induced generation of reactive oxygen species; damage to lipids, proteins, and deoxyribonucleic acids (DNA); and injury to subcellular organelles, including lysosomes and mitochondria, with cellular dysfunction, apoptosis, and necrosis.[25,26] The pattern of the organs affected, the timing of the onset of toxic manifestations, and the severity of tissue damage are known to be influenced by a variety of factors in both hereditary and acquired varieties of systemic iron overload. Within the systemic circulation, these factors include (1) the specific underlying genetic or acquired abnormality; (2) the magnitude of iron excess; (3) the rate of iron loading; (4) the distribution of iron load among more innocuous storage deposits in reticuloendothelial macrophages and potentially injurious accumulations in parenchymal cells of the liver, pancreas, heart, and other organs; and (5) the extent of internal redistribution of iron between reticuloendothelial macrophage and parenchymal sites. Genetic studies suggest that still unidentified genes have substantial effects on iron accumulation and toxicity.[24] In other forms of iron overload, another level of complexity is introduced because the central nervous system, the testes, and the fetus are functionally separate from the systemic circulation and cannot acquire iron directly from plasma transferrin.[27] Instead, iron must be taken up from the systemic circulation by barrier cells and then exported across the blood–brain and blood–cerebrospinal fluid barriers into the brain interstitial and cerebrospinal fluids, across the blood–testis barrier, and across the placenta to the fetus. As a consequence, disorders affecting the proteins responsible for iron supply to these compartments have distinctive manifestations.

Hereditary Iron Overload

Within the systemic circulation, the specific patterns of iron deposition and damage found in the hereditary disorders of iron overload can be characterized by reference to the pathways of internal iron exchange shown in Fig. 33-1 and the classification given in Table 34-4.

In hereditary *HFE*-associated hemochromatosis, an autosomal recessive disorder, the underlying genetic defect in the regulation of hepcidin production results in an inappropriately elevated iron absorption at any level of body iron, with a chronic progressive increase in body iron stores accompanied by enhanced release of iron from reticuloendothelial macrophages.[23,25] The molecular means whereby mutations in *HFE* produce these effects have not been characterized but result in an impaired increase in production of hepcidin in response to iron loading (see Chapter 33). Patients seem unable to effectively upregulate hepcidin expression as iron stores increase. Intestinal iron absorption, although inappropriately high in hereditary *HFE*-associated hemochromatosis, is still regulated by body iron levels. As the body iron level rises as a consequence of increased absorption, circulating transferrin becomes fully saturated. The excess iron is deposited initially predominantly within hepatocytes (Fig. 34-4), but subsequently the iron accumulates in the pancreas, heart, and other organs.[23,25] By the time symptoms of organ damage develop, usually in the fourth or fifth decade of life, body iron stores typically have increased from the normal range of 1 g or less to 15 to 20 g or more. Further increments in body iron stores may be fatal, although some patients are able to tolerate a total iron accumulation of as much as 40 to 50 g. Patients with autosomal recessive hereditary non–*HFE*-associated hemochromatosis caused by mutations in the gene for transferrin receptor 2 seem to be clinically similar to those with the *HFE*-associated form.[23,25] Patients with autosomal recessive juvenile hemochromatosis have the same pattern of tissue iron deposition found in hereditary *HFE*-associated hemochromatosis but develop severe iron overload much earlier, with hypogonadism and cardiac disease manifesting in the second decade of life.[6,23,25] The rate of iron accumulation is increased substantially and is estimated to be three to four times greater than that in *HFE*-associated disease.

Patients with DMT1-associated hemochromatosis have in common a severe microcytic anemia with low hepcidin, high transferrin saturation, and marked hepatic iron deposition but normal to moderately elevated serum ferritin concentration.[6,23,25] Congenital

Table 34-4 Hereditary Iron Overload Disorders

Disorder	Gene, Chromosome Location	Inheritance	Plasma Transferrin Saturation	Plasma Ferritin	Iron Deposition Sites	Clinical Manifestations
Hereditary hemochromatosis, *HFE*-associated (type 1; OMIM 235200)	*HFE*, 6p21	Autosomal recessive	Early increase; >45%	Later increase after third decade	Parenchymal iron overload affecting hepatocytes, heart, pancreas, other organs	Liver and heart disease, diabetes, gonadal failure, arthritis, skin pigmentation
Hereditary hemochromatosis, TfR2-associated (type 3; OMIM 604250)	*TFR2*, 7q22	Autosomal recessive	Early increase; >45%	Later increase after third decade	Parenchymal iron overload affecting hepatocytes, heart, pancreas, other organs	Liver and heart disease, diabetes, gonadal failure, arthritis, skin pigmentation
Juvenile hemochromatosis, hemojuvelin-associated (type 2A; OMIM 602390)	*HJV*, 1q21	Autosomal recessive	Early increase; >45%	Increased by second decade	Parenchymal iron overload affecting hepatocytes, heart, pancreas, other organs	As for hereditary hemochromatosis, but liver involvement less prominent
Juvenile hemochromatosis, hepcidin-associated (type 2B; OMIM 613313)	*HAMP*, 19q13	Autosomal recessive	Early increase; >45%	Increased by second decade	Parenchymal iron overload affecting hepatocytes, heart, pancreas, other organs	As for hereditary hemochromatosis, but liver involvement less prominent
Hemochromatosis, DMT1-associated (OMIM 206100)	*SCL11A2*, 12q13	Autosomal recessive	Early increase; >45%	Normal to moderately elevated	Hepatic iron overload, predominantly in hepatocytes	Severe microcytic anemia, liver dysfunction
Atransferrinemia (OMIM 209300)	*TF*, 3q22	Autosomal recessive	No plasma transferrin	Increased	Parenchymal iron overload affecting hepatocytes, heart, pancreas; no iron in bone marrow or spleen	Transfusion-dependent iron deficiency anemia, growth retardation, poor survival
Aceruloplasminemia (OMIM 604290)	*CP*, 3q24-q25	Autosomal recessive	Decreased	Increased	Marked iron accumulation in basal ganglia, liver, pancreas	Diabetes, progressive neurologic disease, retinal degeneration
Hemochromatosis, ferroportin-associated, with impaired iron export (type 4A; OMIM 606069)	*SLC40A1*, 2q32	Autosomal dominant	Remains normal or low	Early increase	Predominantly macrophage iron deposition	None
Hemochromatosis, ferroportin-associated, with hepcidin resistance (type 4B; OMIM 606069)	*SLC40A1*, 2q32	Autosomal dominant	Early increase; >45%	Early increase	Parenchymal iron overload affecting hepatocytes, heart, pancreas, other organs	Similar to HFE-associated hemochromatosis

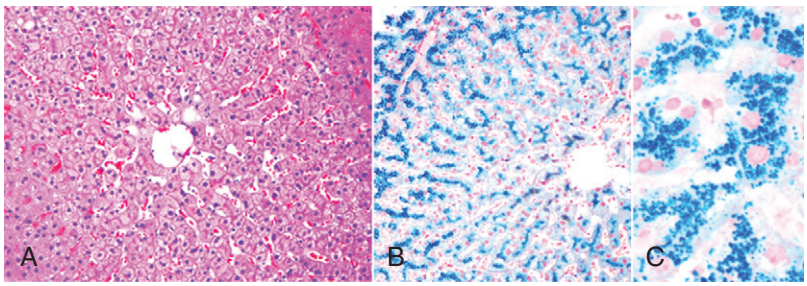

Figure 34-4 HFE-ASSOCIATED HEMOCHROMATOSIS. Liver biopsy sample from a 46-year-old man with homozygous *HFE*-associated hemochromatosis. Hematoxylin and eosin stain of the liver **(A)** shows intact hepatic architecture. Iron stain **(B** and **C)** shows marked diffuse iron deposits in the hepatocytes throughout the lobules. A normal liver would show essentially no iron in the hepatocytes.

atransferrinemia (hypotransferrinemia) is a rare disorder of autosomal recessive inheritance in which plasma transferrin is nearly absent and hepcidin is decreased.[6,23,25] Patients have a severe hypochromic microcytic anemia and die without transferrin infusion or blood transfusions. Hereditary aceruloplasminemia (hypoceruloplasminemia) is a rare disorder of iron homeostasis inherited as an autosomal recessive trait, resulting from absence or severe deficiency of ceruloplasmin occurring as a consequence of mutations in the ceruloplasmin gene.[6,23,25] Patients with aceruloplasminemia typically present in the fourth or fifth decade of life with a triad of diabetes mellitus, progressive neurologic disease (dementia, dysarthria, and dystonia), and retinal degeneration.

Patients with autosomal dominant hemochromatosis resulting from mutations in the ferroportin gene that compromise iron export, such as those resulting in ferroportins that are unable to reach the cell surface to interact with hepcidin, have iron deposition predominantly in macrophages, are almost devoid of clinical manifestations and apparently do not require treatment.[1,23,25] Patients with mutations that result in ferroportins that reach the cell surface but do not respond to hepcidin develop a parenchymal pattern of iron overload that resembles that found in patients with the autosomal recessive forms of hemochromatosis.[1,23,25]

Acquired Iron Overload

Iron-loading anemias may be associated with excessive absorption of dietary iron that can produce severe iron overload. Iron absorption increases dramatically when accelerated erythropoiesis exceeds the ability of transferrin to provide sufficient iron for hemoglobin production[6,26] (see Chapter 33). The iron-loading anemias are characterized by the combination of erythroid hyperplasia with marked ineffective erythropoiesis. Diminished hepcidin production as a result of ineffective erythropoiesis is responsible for the increased iron absorption. These refractory disorders include thalassemia major and intermedia, hemoglobin E/β-thalassemia, congenital dyserythropoietic anemia, pyruvate kinase deficiency, a variety of sideroblastic anemias, and other anemias associated with blocks in the incorporation of iron into hemoglobin. The rate of iron loading is related not to the severity of the anemia but rather to the extent of ineffective erythropoiesis. Patients with nearly normal hemoglobin concentrations may develop massive iron overload and any RBC transfusions will add to the iron burden. Clinical manifestations include liver disease, diabetes mellitus, endocrine disorders, and cardiac dysfunction.

Chronic liver disease with increased absorption of dietary iron may produce mild iron overload in some patients, including individuals with nonalcoholic fatty liver disease (NAFLD), chronic hepatitis C infection, alcohol-related liver disease or portacaval shunts.[28] In porphyria cutanea tarda (see Chapter 36), the most common type of human porphyria, mild hepatic iron overload is found in most patients, and iron depletion by phlebotomy produces clinical and biochemical remission of the disease. African dietary iron overload occurs in sub-Saharan Africa in association with greatly increased dietary iron intake from a traditional fermented beverage with high iron content, but a genetic component not linked to HFE may also be involved.[24] Medicinal iron ingestion can add to the body iron burden of patients with iron-loading disorders, especially iron-loading anemias. In persons without abnormalities affecting iron homeostasis, the extent to which orally administered iron can increase the body iron stores is uncertain.

Parenteral iron overload usually is the result of repeated RBC transfusions in patients with chronic anemia, but occasionally, it is unintentionally produced by repeated injections of iron dextran or other parenteral iron preparations in patients with anemias unresponsive to iron therapy, such as patients undergoing chronic hemodialysis.

Transfusional iron overload progressively develops in patients with chronic refractory anemia who require RBC support (Fig. 34-5).[26] In patients with severe congenital anemias such as thalassemia major (Cooley anemia) or Blackfan-Diamond syndrome, transfusional iron loading begins in infancy. Severe iron loading may develop in transfusion-dependent anemias that appear later in life, namely, aplastic anemia, pure RBC aplasia, hypoplastic or myelodysplastic disorders, and the anemia of chronic renal failure. Patients with sickle cell anemia or sickle cell/β-thalassemia also are at risk for iron overload if chronically given transfusions for prevention of recurrent complications such as stroke, severe infections, and incapacitating painful crises. If ineffective erythropoiesis and erythroid hyperplasia complicate the underlying anemia, increased absorption may contribute to the iron burden. The greater the extent of ineffective erythropoiesis, the greater the suppression of hepcidin synthesis and the greater the magnitude of the increase in iron absorption.

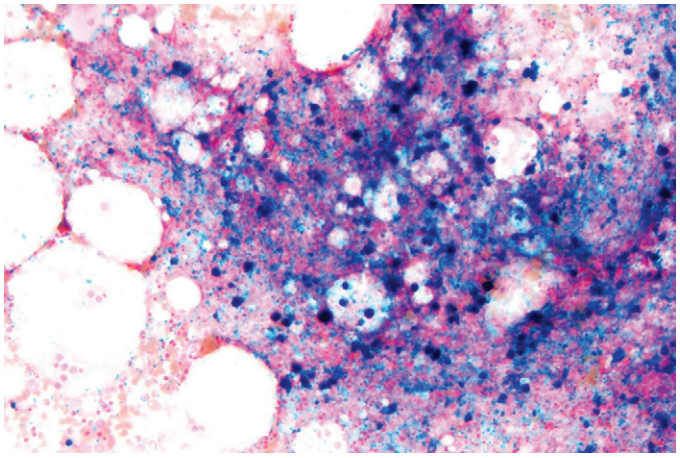

Figure 34-5 ACQUIRED IRON OVERLOAD. Prussian blue–stained bone marrow (BM) aspirate showing excessive iron stores in acquired iron overload. This occurs in a number of instances as discussed in the text, including transfusional iron overload as illustrated here, in the BM of a patient with a myelodysplastic syndrome.

Perinatal iron overload (see Table 34-3) develops in some rare or uncommon metabolic disorders of newborns, apparently as the result of disturbances in the regulation of fetal or maternal–fetal iron balance and in some instances as a result of intrauterine liver disease producing severe hypotransferrinemia.[29] Focal sequestration of iron in other rare disorders produces various patterns of localized iron deposition, in the lung in idiopathic pulmonary hemosiderosis, and in the kidney in renal hemosiderosis. Finally, remarkable progress is being made in elucidating the bases for disorders with specific patterns of brain iron deposition in association with neurologic abnormalities, including Friedreich ataxia, pantothenate kinase-associated neurodegeneration (formerly called Hallervorden-Spatz syndrome), and neuroferritinopathy.[27]

Clinical Presentation

Clinical manifestations of iron toxicity generally develop only in patients with forms of systemic parenchymal iron overload in which the magnitude of iron accumulation is sufficient to produce tissue and organ damage.[23] Individuals at risk include homozygotes for the types of hereditary and juvenile hemochromatosis listed in Table 34-3, some forms of ferroportin-associated hemochromatosis, aceruloplasminemia, and patients with iron-loading anemias, African dietary iron overload, and transfusional iron overload. Patients with forms of iron overload restricted to reticuloendothelial macrophages do not seem to develop clinical complications.[23,25] Specific patterns of neurologic signs and symptoms occur in patients with aceruloplasminemia, pantothenate kinase-associated neurodegeneration, Friedreich ataxia, and neuroferritinopathy that reflect the brain distribution of the excess iron.[27]

In patients with systemic parenchymal iron loading, similar clinical features eventually develop with sufficient iron accumulation to produce organ dysfunction and damage.[23,25,26] At earlier stages, with lower body iron burdens, no distinctive signs or symptoms may be present, and patients may come to attention only because of abnormal laboratory test results. Symptomatic patients may present with any of the characteristic manifestations of parenchymal iron deposition, including liver disease, diabetes mellitus, gonadal insufficiency and other endocrine disorders, cardiac dysfunction, arthropathy, and increased skin pigmentation. Liver disease is the most common complication of systemic iron overload. In all varieties of systemic parenchymal iron overload, the development and severity of liver damage are closely correlated with the magnitude of hepatic iron deposition. Whether derived from increased absorption of dietary iron or from transfused RBCs, progressive parenchymal

iron accumulation eventually produces hepatomegaly, functional abnormalities, fibrosis, and, finally, cirrhosis.[23,25,26] Hepatocellular carcinoma seems to be the ultimate complication of cirrhosis in iron overload. The development of cirrhosis increases the risk of hepatoma by more than 200-fold.

Diabetes mellitus is another common complication of all forms of systemic parenchymal iron overload. Virtually all of the secondary manifestations of diabetes may develop, including retinopathy, nephropathy, neuropathy, and vascular disease. Gonadal insufficiency and other endocrine abnormalities occur. During the second decade of life, both growth and sexual maturation usually are retarded in untreated patients with transfusional iron overload.

Iron-induced cardiac disease, occurring as a cardiomyopathy with heart failure, arrhythmias, or both, may be a fatal complication of all varieties of systemic parenchymal iron overload. Heart disease is the most frequent cause of death in patients with thalassemia major.[7] Severe cardiac disease in particular may be the presenting manifestation in young patients with juvenile hemochromatosis.[23]

Increased skin pigmentation, with a bronze hue in some patients and a slate-gray coloration in others, often accompanies iron overload. Chondrocalcinosis and other forms of arthropathy are common complications of hereditary hemochromatosis and may occur in other forms of systemic parenchymal iron overload. An increased susceptibility to infectious disease may be found in patients with transfusional and other forms of iron overload, especially to infections with certain organisms, including *Vibrio vulnificus, Listeria monocytogenes, Yersinia enterocolitica, Escherichia coli, Candida* spp., and *Mycobacterium tuberculosis*.[4]

Laboratory Evaluation

The typical sequences of changes in clinically useful indicators of iron status as body iron increases from the iron-replete normal to the amounts found in hereditary hemochromatosis and transfusional iron overload are shown in Fig. 34-1. Characteristic changes in laboratory measures of iron status in the disorders of hereditary iron overload are listed in Table 34-4.

Screening for iron overload can use phenotypical methods, genotypical methods, or both.[23,25] Phenotypical screening can provide biochemical evidence of iron overload in patients with hereditary or juvenile hemochromatosis but does not identify all persons genetically at risk for iron loading. In populations of northern European ancestry, genotypical screening for the C282Y and H63D mutations in HFE can identify most persons at risk for developing hereditary hemochromatosis but gives no information about the presence or magnitude of iron overload. In most clinical circumstances, a combination of phenotypical and genotypical methods is the best strategy for screening.[24]

In individuals of northern European ancestry, measurement of the serum transferrin saturation usually is the best method for initial phenotypical screening for systemic parenchymal iron overload.[23-25] A persistent value of 45% or greater often is recommended as a threshold value for further investigation. In the absence of complicating factors, elevated concentrations of serum ferritin provide biochemical evidence of iron overload. Genetic testing then should be considered in persons with abnormal transferrin saturation, serum ferritin concentration, or both. Liver biopsy may be indicated for prognostic purposes to detect cirrhosis if the serum ferritin concentration is greater than 1000 μg/L and may be contemplated in the presence of hepatomegaly or abnormalities on liver function testing, or in patients older than 40 years.

Persons with phenotypical evidence of iron overload who are neither C282Y/C282Y homozygotes nor C282Y/H63D heterozygotes can be considered for further genetic testing for less common *HFE* mutations and for non-*HFE* mutations associated with iron loading, for noninvasive assessment of the liver iron concentration, or for diagnostic liver biopsy.

Liver biopsy can establish a definitive diagnosis of hereditary and juvenile hemochromatosis regardless of genotype and can demonstrate the histologic pattern of iron loading found with ferroportin mutations or with chronic liver diseases (NAFLD, chronic hepatitis C infection, and alcohol-related liver disease) (see box on Testing for Iron Overload). A quantitative determination of the nonheme iron concentration in the liver sample should be made, the pattern of iron deposition examined histochemically, and the extent of tissue injury assessed histopathologically. In patients found to have an increased body iron load, additional clinical and laboratory studies should seek evidence of complications of iron overload. Further investigation may include liver function testing; testing for diabetes mellitus; evaluation of hormonal function; cardiac examination; joint and bone radiography examination; and, especially if cirrhosis is present, screening for hepatocellular carcinoma.

Testing for Iron Overload

A direct measure of body iron avoids the uncertainties inherent in the interpretation of indirect indicators of iron status. Liver biopsy is the definitive direct test for assessing iron deposition and tissue damage in iron overload, permitting measurement of the nonheme iron concentration, histochemical determination of the cellular distribution of iron between hepatocytes and Kupffer cells, and pathologic examination of the extent of tissue injury.[23,25] When available as appropriately calibrated and validated techniques, new noninvasive methods using hepatic magnetic susceptibility and magnetic resonance imaging (MRI) may replace liver biopsy when only determination of the liver iron concentration is needed. MRI studies of the heart are particularly useful in patients at risk for cardiac iron deposition.[7] In patients with hereditary hemochromatosis undergoing therapeutic venesection, quantitative phlebotomy provides an accurate retrospective determination of the amount of storage iron that can be mobilized for hemoglobin formation.[24] When liver biopsy is contraindicated in a patient, quantitative phlebotomy occasionally is useful in establishing the diagnosis of hereditary hemochromatosis. BM aspiration and biopsy provide no information about the extent of parenchymal iron loading and are of limited value in the evaluation of iron overload. Iron overload produces no specific abnormalities in the peripheral blood.

Atransferrinemia or hypotransferrinemia is readily demonstrable by measurement of the plasma transferrin concentration. Similarly, aceruloplasminemia or hypoceruloplasminemia can be diagnosed by measurement of the plasma ceruloplasmin concentration. For detection and diagnosis of iron-loading anemias, measurement of the plasma transferrin receptor and examination of the BM may be helpful in demonstrating ineffective erythropoiesis in combination with the erythroid hyperplasia characteristic of these disorders.

Differential Diagnosis

Detection and diagnosis of iron overload are most problematic in the hereditary forms of iron overload (see Table 34-3). A combination of phenotypical and genotypical screening should lead to a definitive diagnosis in most patients. Aceruloplasminemia is a rare disorder, but distinguishing this form of iron overload from hereditary hemochromatosis is important in guiding effective iron-chelating therapy that can prevent or arrest neurologic damage.

In patients with iron-loading anemias who are not transfusion dependent, the severity of anemia provides no indication of the risk of iron loading from increased dietary iron absorption. Patients with only minor degrees of anemia may accumulate major iron loads. The differential diagnosis directed at the remaining causes of iron overload listed in Table 34-3 poses few problems. Porphyria cutanea tarda is discussed more fully in Chapter 36 and is readily diagnosed by the measurement of urinary porphyrins. The source of iron overload in patients with parenteral iron loading is evident, whether from

repeated injections of therapeutic iron or from transfusion. The various causes of perinatal iron overload are clearly distinguished by clinical and pathologic findings. The diagnosis of idiopathic pulmonary hemosiderosis should be considered whenever iron-deficiency anemia develops with coexisting pulmonary abnormalities. Previously, the demonstration of iron deposits in the brain of patients with Friedreich ataxia, pantothenate kinase-associated, and neuroferritinopathy was possible only at autopsy, but MRI now provides a means for detecting localized brain iron deposits during life.[27]

Patients with hyperferritinemia but no clinical manifestations or elevated transferrin saturations may have mutations in the ferroportin gene (see Table 34-4) or in the gene for the iron-responsive element in L-ferritin messenger RNA. The latter mutations are responsible for hereditary hyperferritinemia with cataract, a disorder of autosomal dominant inheritance in which affected family members present with early-onset bilateral nuclear cataracts and moderately elevated plasma ferritin concentrations caused by increased concentrations of L-ferritin.[6] Serum iron concentration and transferrin saturation are normal or low, body iron level as evaluated by phlebotomy is not increased, and no hematologic or biochemical abnormalities are evident in affected persons. Molecular studies have identified mutations in the iron-responsive element of the L-ferritin messenger RNA as responsible. The only sign of the mutation seems to be an accumulation of L-type ferritin in the lens, resulting in cataract formation.

Therapy

The goal of therapy for iron overload is reduction and maintenance of body iron at normal or near-normal levels. If possible, phlebotomy is the treatment of choice for hereditary hemochromatosis,[23,25] iron-loading anemia if the hemoglobin concentration is high enough to permit venesection, porphyria cutanea tarda, and African dietary iron overload. After the diagnosis of iron overload has been established, phlebotomy therapy should begin promptly because any delay extends exposure to potentially toxic iron accumulations.

For most patients, phlebotomy should remove 500 mL of blood, containing 200 to 250 mg of iron, once weekly, until storage iron is depleted.[23,25] The regimen should be individualized. For patients with iron-loading anemia, smaller amounts of blood will need to be withdrawn weekly, but for heavily iron-loaded patients with hereditary hemochromatosis, an even more vigorous program of twice-weekly phlebotomy can be used. The hematocrit or hemoglobin concentration should be measured before each phlebotomy procedure. The progress of iron removal can be followed by periodic measurements of plasma ferritin and iron concentrations and transferrin saturation. The plasma ferritin concentration declines progressively as iron is removed, but the plasma iron concentration and transferrin saturation remain elevated until iron stores near depletion. In a patient with porphyria cutanea tarda, a few weeks of phlebotomy will suffice, but in a patient with hereditary hemochromatosis and an initial body iron burden of 25 g, removal of the iron burden may require 2 years or more of phlebotomy. After complete removal of the iron load, lifelong maintenance therapy is needed, usually necessitating phlebotomy of 500 mL every 3 to 4 months or, in some patients, even less frequently.

For patients with transfusion-dependent refractory anemias, most patients with iron-loading anemias, and rare patients with hereditary hemochromatosis in whom phlebotomy is impossible, treatment with an iron chelator is the only means of preventing or removing toxic accumulations of iron[26] (see box on Timing of Chelation Therapy). In patients with hereditary hemochromatosis and cardiac failure, a combination of phlebotomy and chelation therapy has been recommended. In the United States, two iron-chelating agents are available for initial treatment of transfusional iron overload, deferoxamine, given parenterally, and deferasirox, administered orally.[26] A third iron chelator, oral deferiprone, is approved in the United States, the European Union and other countries for patients with thalassemia major when deferoxamine is contraindicated or inadequate.

Timing of Chelation Therapy

In all forms of transfusional iron overload, the most effective means of avoiding complications is to prevent excessive iron accumulation with early iron-chelating therapy.[26] In patients who are transfusion dependent from early infancy (i.e., those with thalassemia major or other congenital refractory anemias), chelation therapy is best started after 10 to 20 transfusions, usually at approximately 3 years of age. In older patients with acquired refractory anemias who become transfusion dependent, it seems advisable to begin chelation early after transfusion of 10 to 20 units of blood. In patients with iron-loading anemias and those with sickle cell disease who are chronically transfused for prevention of complications, early therapy also seems prudent. In each of these disorders, delay in beginning chelation therapy only exposes the patient to a greater risk of iron toxicity.

Over the past 4 decades, clinical experience with deferoxamine, a hexadentate bacterial siderophore purified from *Streptomyces pilosus,* has established the efficacy and safety of this agent in preventing organ dysfunction and prolonging survival in patients with transfusional iron overload.[26] Unfortunately, deferoxamine given orally is poorly absorbed. To be effective, the drug must be administered by prolonged subcutaneous or intravenous infusion with a small portable syringe pump, ideally each day, making compliance a demanding task. In patients with modest iron loads and no evidence of iron toxicity, slow subcutaneous infusion of deferoxamine for 9 to 12 hours daily usually provides adequate therapy. In severely iron-loaded patients and in patients with evidence of iron toxicity, particularly those with cardiac complications, chronic slow intravenous infusions given through an indwelling central venous catheter may permit more rapid reduction of the body iron burden. Deferoxamine is a generally safe and nontoxic drug for iron-loaded patients, but systemic complications have been reported, including allergic anaphylactoid reactions, infectious complications, visual abnormalities, auditory dysfunction, and growth retardation. The risk of many of these complications may be minimized by adjusting the deferoxamine dose to the magnitude of the body iron load. Adequate deferoxamine therapy should produce a progressive decrease in the body storage iron of almost any patient with iron overload. If no decline is observed, blood and deferoxamine use, compliance, ascorbate status, and other features of the therapeutic regimen should be thoroughly reassessed.

Deferasirox, a synthetic orally active tridentate iron chelator, was approved for use by the U.S. Food and Drug Administration in 2005 for treatment of transfusional iron overload in adults and children older than 2 years.[30] Deferasirox has a long plasma half-life, making possible once-daily dosing. Extensive systematic clinical trials in patients with thalassemia major, sickle cell disease, and other transfusion-dependent anemias have provided evidence that the effectiveness of deferasirox in the management of iron overload is comparable to that of deferoxamine.[30] The most common adverse events have been rash, gastrointestinal disturbances, and abnormalities in renal function. Additional clinical studies examining the long-term safety and efficacy of deferasirox are in progress, but the initial 5 years of experience with this drug suggests that this orally active iron-chelating agent is a well-tolerated, once-daily treatment for control of transfusional iron overload.[30] Despite the lack of data on long-term effectiveness, most patients now opt for deferasirox because of the ease of oral administration.

Prognosis

The prognosis in patients with iron overload is influenced by many factors, including the magnitude, rate, and route of iron loading; distribution of iron deposition between reticuloendothelial macrophage and parenchymal sites; amount and duration of exposure to

circulating non–transferrin-bound iron; ascorbate status; and coexisting disorders, especially alcoholism.[23,25] The magnitude of iron accumulation seems to be a critical determinant of the risk of cirrhosis of the liver and, in turn, of hepatocellular carcinoma, now the two major causes of death in hereditary hemochromatosis. If the disease is diagnosed before tissue injury occurs, phlebotomy therapy to remove the excess iron can prevent all of the complications of hemochromatosis, including cirrhosis, and return the patient's life expectancy to normal.[23,25] Even if organ damage is present, phlebotomy prevents further progression, and amelioration of some features of the disease is possible. Skin pigmentation diminishes; hepatic function may improve while fibrosis is arrested or sometimes regresses; and cardiac abnormalities, including even cardiac failure, may resolve. Diabetes and other endocrine abnormalities usually are ameliorated only slightly, if at all, although reversal of hypogonadism has occurred. Arthropathy usually does not subside and may even continue to progress despite phlebotomy.

In patients with iron overload who cannot be treated by phlebotomy, chelation therapy is effective in reducing the body iron burden and improving the prognosis. Orally administered deferasirox or chronic infusion of parenteral deferoxamine decreases the hepatic iron concentration, improves hepatic function, promotes growth and sexual maturation, and helps protect against cardiac disease and early death. In all forms of iron overload, the most effective means of preventing complications is prevention of iron accumulation, either by early identification and phlebotomy treatment of hereditary hemochromatosis or by early institution of chelation therapy in patients with iron-loading or transfusion-dependent anemias.

CHAPTER 35

ANEMIA OF CHRONIC DISEASES

Jane A. Little, Edward J. Benz, Jr., and Lawrence B. Gardner

Anemia is commonly associated with many diverse systemic inflammatory conditions, including infection, rheumatologic disorders, and cancer. The cause of the anemia of chronic disease (ACD) is multifactorial and includes both inhibition of red blood cell (RBC) production (caused by a combination of dysregulated iron metabolism, inhibited hematopoiesis, and relative erythropoietin deficiency) and a mildly decreased RBC lifespan. Teleologically, ACD may serve to decrease infectious virulence by organisms, such as malaria and schistosomiasis, in a nutrient-depleted host.[1-4] Malignancies may also be potentiated in an iron-rich environment in humans.[5-8] Research over the past decade has delineated the important pathophysiological role of inflammatory cytokines in ACD. Once described as a "bag of unsolved questions,"[9] the pathophysiologic underpinnings of ACD have been dramatically illuminated by the recently characterized antimicrobial peptide hepcidin. Hepcidin is both a mediator of innate immunity and an iron regulatory peptide, and it plays a major, although not solo, role in the pathogenesis of ACD.

DESCRIPTION AND EPIDEMIOLOGY

Anemia of chronic disease is an anemia of underproduction that usually is relatively mild, with hemoglobin levels typically greater than 10 g/L, normocytic, and normochromic.[10] However, the anemia can be severe, and the mean corpuscular volume may be reduced, sometimes dramatically, in up to one-third of patients. ACD is one of the most common causes of anemia. Over a 2-month period of observation, 52% of hospitalized patients with anemia who were not iron deficient, hemolyzing, or with a hematologic malignancy met laboratory criteria for ACD.[11] An unselected elderly population (older than 60 years of age), followed prospectively, had a 2.4% 3-year incidence of ACD.[12,13] Anemia (hemoglobin <12 g/dL) is extremely common in cancer, seen in 58% of 420 subjects with nonhematologic malignancies before radiation therapy and in one- to two-thirds of general oncologic populations.[14,15] The presence of anemia may inversely correlate with response to cancer therapy[16] and survival.[17] HIV infection is often associated with anemia, particularly as the infection progresses to clinical AIDS (increasing from a prevalence of one-tenth to one-third).[18] ACD is common in outpatients with rheumatoid arthritis (prevalence of 25%-30%), and the degree of anemia is associated with an elevation in some markers and/or mediators of inflammation, such as sedimentation rate (ESR), C-reactive protein CRP, and interleukin-6 (IL-6).[19-21]

Although most hospitalized patients with ACD have an active infection, inflammatory condition or malignancy, other reported precipitating illnesses include alcoholic liver disease, congestive heart failure, thrombosis, chronic pulmonary disease, diabetes, trauma, and a variety of other medical conditions.[11,22] It is intriguing that diverse diseases, not conventionally considered "inflammatory" in nature, such as congestive heart failure, obesity, renal failure, and diabetes, have been associated both with an ACD-type anemia and with cytokine abnormalities more typically associated with inflammatory condition (e.g., elevated Il-6 and CRP in kidney disease or CRP and fibrinogen in myocardial infarction).[6,11,23-25] Because of the absence of definitive diagnostic criteria or definitive lab tests (as discussed in Diagnosis), however, epidemiologic studies in ACD are at the least confounded by the underlying clinical heterogeneity.

ETIOLOGY AND PATHOGENESIS

Anemia of chronic disease is marked by low serum iron. However, in contrast to iron-deficiency anemia, total iron stores are normal or elevated. In rheumatoid arthritis, this low serum iron and depressed hemoglobin parallel disease activity, not patient age or duration of disease.[26] Because of characteristic abnormalities in laboratory iron studies, initial theories on the etiology of ACD emphasized the role of iron. Recent descriptions of elevated hepcidin levels in ACD and of hepcidin's preeminent role in regulating iron utilization have reinforced an emphasis on the role of iron metabolism in ACD (see Biology and Molecular Aspects). However, iron-centered models do not account for concurrent evidence for the suppression of hematopoiesis, the relative deficiency of erythropoietin (EPO), and the shortened RBC half-life that are also seen in ACD. Interestingly, there is also evidence for a hepcidin-mediated effect on erythroid progenitor proliferation and survival.[13,27] Some inflammatory cytokines may increase hepcidin levels while also suppressing erythropoiesis and shortening RBC half-life. It is clear that the pathogenesis of ACD is multifactorial and complex (Table 35-1).

Although a variety of studies demonstrate that RBC survival in ACD is only mildly decreased, this may be sufficient to depress the hemoglobin concentration when erythropoiesis is concomitantly suppressed (see Biology and Molecular Aspects). A mildly shortened erythrocyte half-life has been observed in patients with rheumatoid arthritis and ACD. Experimentally, rats given endotoxin have a reduced erythrocyte half-life[28] and transgenic mice with elevations in the cytokine interferon-γ (IFN-γ) have a reduced RBC half-life because of removal of RBCs by cytokine-stimulated splenic macrophages.[29] Exogenous administration of IFN-γ in mice likewise increases RBC uptake and hemophagocytosis by macrophages.[30]

Iron metabolism is deregulated in ACD. Early studies in a variety of animal models demonstrated that radiolabeled iron absorption and half-life were diminished in the presence of systemic inflammation.[28,31] Other studies using trace quantities of labeled iron showed no direct impairment of iron incorporation into RBCs, suggesting that inflammation preferentially impairs iron release from storage sites, decreases plasma iron concentration, and limits iron incorporation during hemoglobin synthesis. Sterile inflammation in a dog model impairs only the reuse of iron from senescent RBCs, implying that inflammation primarily leads to a defect in iron release from tissues to the plasma transferrin pool.[32] Studies in patients with rheumatoid arthritis and a diagnosis of ACD also demonstrate decreased iron turnover compared with normal or iron-deficient control participants.[33] As discussed later, hepcidin's molecular mechanism of action (degradation of ferroportin) is consistent with a prominent disruption in release of iron from storage sites.

Abnormal iron turnover in ACD may occur via several mechanisms. Decreased transferrin receptors in the serum[18] and on

Direct inhibition of erythropoiesis
Relative deficiency of erythropoietin

erythroblasts[34] are seen in patients with ACD. Investigators have suggested that an increased release of lactoferrin from neutrophils[35] or an increased synthesis of apoferritin[36] may lead to a pool of iron trapped in storage form that is unavailable for hemoglobin synthesis. More recently, hepcidin has been implicated in ACD. Hepcidin, a small, circulating antimicrobial peptide, binds to the iron export channel ferroportin, resulting in its phosphorylation, internalization, and degradation.[37] This diminution in ferroportin density on the plasma membrane results in decreased iron absorption from duodenal cells and blocked iron release from ferroportin-expressing macrophages and hepatocytes and leads to a net decrease in the absorption of biologically available iron.[13,38,39] Diminished iron absorption in the duodenum and decreased serum iron coupled with enhanced iron retention in the macrophages (visible on bone marrow examination) cause a redistribution of total body iron. Ferroportin is also present and functional on erythroblasts.[40] Net iron retention in the erythroblast, when ferroportin is degraded by hepcidin, despite decreased serum iron levels may explain the typical normochromic, normocytic nature of ACD. Experimental overexpression of hepcidin leads to a fatal anemia in mice, with a decrease in iron absorption and an increase in reticuloendothelial stores of iron.[41] Hepcidin is increased in inflammatory conditions in mice (see Biology and Molecular Aspects later) and is elevated in a variety of diseases associated with ACD.[42] Together, these data suggest that hepcidin is a major mediator for many of the iron changes seen in ACD.

In addition to a decrease in an important hemoglobin precursor (i.e., iron), a direct inhibition of hematopoiesis and a relative deficiency of EPO are found in ACD. This inhibition of hematopoiesis has been attributed to soluble factors, now known to be cytokines, present in the perturbed bone marrow microenvironment (see Biology and Molecular Aspects later). Studies have shown that removal of bone marrow–adherent cells (mostly macrophages and monocytes) from patients with ACD leads to increased erythroid colony formation. This process can be reversed by co-culture of ACD-adherent cells but not by adherent cells from control bone marrow.[43] Culture with serum from patients with rheumatoid arthritis and anemia produces decreased burst-forming unit-erythroid (BFU-E) proliferation, but serum from nonanemic arthritic patients does not.[44] Peripheral blood mononuclear cells from patients with rheumatoid arthritis also suppress BFU-E growth.[45]

Most of the supporting data for direct inhibition of hematopoiesis are derived from in vitro studies. Data from more clinically relevant studies have clearly documented a relative deficiency of EPO in many chronic diseases associated with anemia. In a study of 81 patients with solid tumors who exhibited laboratory data compatible with ACD and who did not have bone marrow involvement by tumor, EPO levels were higher than in control participants without anemia but were only half the values typical of subjects with similar hematocrits caused by iron deficiency. The normal inverse relationship between hemoglobin and EPO levels also was not seen.[46] In 41 anemic patients with rheumatoid arthritis, 14 of whom had plentiful iron on bone marrow aspirate, serum EPO levels were lower than for those with simple iron-deficiency anemia despite comparable hemoglobin levels.[47] Serum EPO levels have been shown to be inappropriately low in human immunodeficiency virus (HIV)–positive patients with normochromic, normocytic anemia[48] and in lung transplant recipients.[49]

Patients with diabetes with anemia, normal renal function, and lower-than-expected EPO levels have been reported. This condition is hypothesized to be caused by diabetic neuropathy,[50] although there also may be a direct role of insulin on stem cells.[51] Up to 40% of patients with chronic liver disease are anemic. Although this anemia is clearly multifactorial, some studies have found a blunted EPO response to anemia in patients with cirrhosis,[52] but other studies have not.[53] The observation that hepcidin synthesis may be altered in liver disease is likely to provide further insight into ACD in this setting.[54]

Finally, EPO may not function optimally in the presence of inflammatory cytokines. EPO-resistant subjects with end-stage renal disease are more likely to have elevations in inflammatory cytokines.[55] Similarly, peripheral blood mononuclear cells isolated from EPO-refractory subjects with end-stage renal disease are more likely to produce inflammatory cytokines than those isolated from nonrefractory subjects.[56]

BIOLOGY AND MOLECULAR ASPECTS

The role of inflammatory cytokines in many of the underlying diseases associated with ACD has suggested a mechanistic link for much of the pathophysiology of anemia, including decreased erythrocyte survival, decreased access to available iron through upregulation of hepcidin and other mechanisms, direct inhibition of hematopoietic progenitor growth, and inadequate EPO response to anemia.

Increased serum levels of cytokines, particularly IL-1, IL-6, IL-10, tumor necrosis factor (TNF), IFN-α, IFN-β, and IFN-γ, have been observed in many inflammatory diseases, including HIV, hepatitis C, tuberculosis, bacterial and fungal infections, rheumatoid arthritis, inflammatory bowel diseases, and both solid and hematologic malignancies.[57-59] Elevated levels of several cytokines have been found in patients with malarial infections, partly caused by plasmodium-induced stimulation of macrophages.[60] TNF-α synthesis is increased in mucosal T cells in patients with Crohn disease[61] and in blood mononuclear cells from patients with rheumatoid arthritis.[62] High levels of inflammatory cytokines may be concentrated in the bone marrow milieu. Bone marrow of patients with rheumatoid arthritis has increased levels of IL-6 and TNF-α.[63] Bone marrow stromal cells in patients with giant cell arteritis may produce less stem cell factor and granulocyte-macrophage colony-stimulating factor than do control participants.[62]

The fact that cytokines are thought to play such an important role in many of the diseases associated with anemia and that levels of many of these cytokines often correlate with the degree of anemia suggests an association between inflammatory cytokines and anemia. Indeed, serum TNF-α levels correlate with both disease activity and the degree of anemia in rheumatoid arthritis.[64] Experimentally, transgenic mice with endogenous elevations in IFN-γ show increased expression of the proleukocyte transcription factor PU.1 in hematopoietic precursors and diminished BFU-E.[29] Causality is also suggested by the multiple trials of cytokine antagonists in inflammatory diseases that have shown a decrease in anemia.[65-67] Many molecular mechanisms by which cytokines directly or indirectly affect hematopoiesis have been described.

Cytokine-Induced Decreases in Red Blood Cell Survival

Several studies suggest a role for decreased erythrocyte survival in the pathogenesis of ACD. Alterations in RBC rheology (deformability and aggregation) are demonstrably abnormal in intensive care unit patients, especially those with sepsis.[49] In vivo and in vitro experiments have suggested that fever itself can induce rheologic changes in erythrocytes within a few days, leading to increased destruction and up to a 15% decline in RBC mass.[68] Recent studies have shown that cytokines, the cause of fever in many of the diseases associated with ACD, may directly alter RBC kinetics. For example, rats receiving chronic intraperitoneal injections of IL-1 and TNF showed decreased erythrocyte survival, as did mice with high levels of IFN-γ.[42,43] This effect has been postulated to involve cytokine-induced macrophage and reticuloendothelial system activation.[28,42,43]

Cytokine-Induced Abnormalities in Iron Metabolism

Many of the cytokines implicated in ACD have associated effects on iron metabolism. Nude mice inoculated with TNF-α–secreting Chinese hamster ovary cells showed an almost 60% decline in serum iron after 3 weeks while maintaining normal bone marrow stores of iron.[69] Rats injected with IL-1 or TNF experienced a 40% drop in serum iron levels; TNF also caused a significant decrease in iron incorporation into erythrocytes.[28] These findings are consistent with the observation that iron reuse is defective in ACD.[32] TNF has also been shown to increase radiolabeled iron uptake by peritoneal macrophages without an increase in iron release,[32,70,71] suggesting that macrophage sequestration of iron is cytokine induced. In clinical trials, IL-10 led to anemia in patients with Crohn disease and to an increase in ferritin levels, decreasing iron availability to RBC precursors.[59]

Molecular evidence implicates a direct cytokine effect on iron metabolism. IL-1β increases ferritin translation via a 5′ untranslated region, distinct from the well-known iron responsive element but similar to a 38-nucleotide consensus sequence found in other IL-sensitive acute-phase reactants.[72,73] Because this increase in ferritin synthesis occurs without increased cellular transferrin receptor transcription or expression and involves no new iron influx, IL-1 could lead directly to the creation of an intracellular iron pool that is not available for hemoglobin synthesis.[73] IL-10 also appears to increase ferritin translation.[59]

Importantly, more recent data demonstrate that inflammatory cytokines upregulate hepcidin, which, as previously noted, likely mediates many of the iron changes seen in ACD. Hepcidin is primarily regulated transcriptionally. Although IL-1α, IL-1β, IFN-γ, and other inflammatory cytokines upregulate hepcidin expression in vitro,[74,75] compelling experimental data have most closely linked IL-6 (and IL-6–like family members)[50] and the bone morphogenetic proteins (BMPs) as the most important inducers of hepcidin mRNA expression.[76-79]

The association between individual cytokines, hepcidin, iron metabolism, and ACD are more complicated in vivo. In anemia of the elderly, Il-6 and CRP levels, but not urinary hepcidin levels, were inversely correlated with serum iron levels.[31] In 65 subjects with Hodgkin disease, anemia was associated with increased IL-6 and hepcidin levels.[80] In subjects with multiple myeloma, in whom serum IL-6 and BMP levels are often elevated,[5,81] normochromic, normocytic anemia (absent renal disease) correlates with urinary and serum hepcidin levels, as well as IL-6 levels,[57] but hepcidin elevations were experimentally associated with elevated BMP-2 levels in patients' sera, rather than to alterations in IL-6.[59,81] Furthermore, in animal models of ACD, in vivo antagonists of either hepcidin or of BMP signaling have been shown to prevent IL-6 and inflammation-associated anemia.[82,83]

The transcription factors STAT3 (signal transducer and activator of transcription 3)[79,84] and SMAD4 (Sma and Mad related protein),[85] both of which are upregulated by IL-6 and other inflammatory cytokines via BMP type I receptors,[86] activate the hepcidin promoter and induce hepcidin mRNA. In humans, injection with lipopolysaccharide dramatically increases IL-6 levels by hour 3 followed by an increase in urinary hepcidin by hour 6.[87] Direct administration of IL-6 to humans also leads to increased urinary hepcidin and decreased serum iron.[39] In patients with ACD, increased pro-hepcidin serum concentrations are associated with decreased expression of ferroportin along with increased ferritin accumulation in circulating monocytes.[88]

Finally, the physiological regulation of hepcidin is complicated by a number of experimental studies that have suggested that EPO and its downstream signaling molecules may downregulate hepcidin expression despite the presence of inflammatory cytokines.[89,90] Clinical and experimental data have suggested that EPO and its downstream signaling molecules are better at countervening inflammatory-mediated induction of hepcidin than is hypoxia.[89,91] The signals that regulate hepcidin may be hierarchically determined rather than additive.

Cytokines Leading to Direct Inhibition of Hematopoiesis

Although data demonstrate that cytokines, including IL-1, IFN, and TNF, can have a direct inhibitory effect on hematopoiesis, almost all of the evidence supporting such a role for cytokines is derived from in vitro experiments, and the clinical relevance is unclear. The role of IL-6 in the direct inhibition of hematopoiesis is controversial. Exogenous IL-6 given to monkeys causes a dose-dependent, mild, short-lived anemia within 4 weeks.[92] Some studies have shown that IL-6 has direct inhibitory effects on stem cells.[93] However, other studies have demonstrated that IL-6, which is elevated in rheumatoid arthritis, has no direct effect on bone marrow hematopoiesis.[94] Juvenile-onset chronic arthritis is associated with increased IL-6 levels and anemia, but this anemia is one of iron deficiency.[95] IL-6 also has been shown to cause bleeding in the rat intestinal wall[63] and, as discussed, can also upregulate hepcidin. In vitro studies have demonstrated that colony-forming unit-erythroid (CFU-E) formation is diminished at low EPO conditions when hepcidin is added, which may be attributable to proapoptotic functions of hepcidin.[27]

There is much better evidence for the role of IFN in the direct inhibition of erythropoiesis. IFN-γ can inhibit highly purified CFU-E from mice spleens in a dose-dependent manner.[96-98] Bone marrow stromal cells, retrovirally engineered to secrete IFN-γ, inhibit hematopoiesis in long-term bone marrow cultures by blocking cell cycle progression and inducing apoptosis in CD34 cells to a much greater degree than exogenous IFN.[99] IFN inhibition can be reversed by exogenous addition of murine IFN-γ receptors.[97] Inhibition by IFN-γ can also be reversed in a dose-dependent manner by EPO, a phenomenon seen in ACD,[96,97,100] and partial reversal can be achieved by stem cell factor.[101] The concentration of IFN-γ required to suppress BFU-E is less than that needed to suppress CFU-E, suggesting the suppression occurs at the earlier stages of erythroid development.[98] Similar to IFN-γ, IFN-β appears to act directly on CFU-E, and inhibition does not require accessory T cells or adherent bone marrow cells.[97,102] Inhibition by IFN-α appears to work indirectly. Inhibition by IFN-α or IFN-β is not reversed by EPO.[97]

Tumor necrosis factor serum levels correlate with the degree of anemia in ACD. Erythroid growth is increased in the bone marrow of control and chronically anemic patients by monoclonal antibodies against TNF.[64] Transplantation of a Chinese hamster ovary cell line transfected with the human TNF gene led to anemia in nude mice within 3 weeks, with a significant decrease in BFU-E and CFU-E.[69] Exogenous TNF decreases erythroid colony formation.[64] For example, the inhibition of BFU-E growth sustained by normal bone marrow cultured in the presence of peripheral blood mononuclear cells of patients with rheumatoid arthritis can be reversed by antibodies to TNF-α.[45] However, evidence indicates that the effect of TNF on hematopoiesis is indirect, mediated by the local release of other cytokines, including IFN from accessory cells.[96] The inhibitory effect of TNF on CFU-E was completely abrogated by neutralizing antibodies against IFN-β but not by antibodies to IFN-γ or IL-1.[57] The effects of IL-1 also appear to be indirect. Growth of purified CFU-E is inhibited by recombinant IL-1 only in the presence of adherent T lymphocytes. The inhibition can be reversed by antibodies to IFN-γ, suggesting that IL-1 leads to lymphocyte secretion of IFN.[102]

Cytokines Leading to Decreased Erythropoietin Secretion

Cytokines have been implicated in the blunted, inappropriately low EPO levels seen in ACD. In the EPO-producing human hepatoma cell line HepG2 grown in diffusion-limited oxygen conditions, IL-1α, IL-1β, and TNF-α significantly lowered EPO production. IL-1β also inhibited EPO production in perfused rat kidneys. In these well-controlled experiments, the effect was specific and not secondary to a generalized inhibitory growth effect.[103] Using another hepatoma cell line, Hep3B, hypoxia-driven EPO production was

inhibited with IL-1α, IL-1β, and TNF-α in a dose-dependent, additive manner.[93] Other soluble factors, in addition to cytokines, may play a role in directly inhibiting EPO in ACD. Animal models have suggested that vascular endothelial growth factor, which is commonly elevated in cancer, wounds, and ischemia, may act as a negative regulator of EPO synthesis,[104] thus suggesting a potential link between diverse systemic illnesses and EPO deficiency.

Perhaps one of the strongest arguments for a causative role of EPO in ACD is that exogenous EPO can at least partially reverse ACD. However, supraphysiologic levels of EPO may simply overcome a direct inhibition of erythropoiesis (see Treatment later). Inhibition by IFN-γ can be reversed by EPO.[100] Moreover, the capacity of monocytes from patients with inflammatory bowel disease to secrete TNF predicts therapeutic response to exogenous EPO.[105]

DIAGNOSIS

Because ACD is a multifactorial disease and is seen in many clinical settings, an unequivocal diagnosis may be difficult. Many chronic illnesses are associated with other factors leading to anemia, including iron and nutritional deficiency, bleeding, hemolysis, renal failure with absolute EPO deficiency, and bone marrow fibrosis or infiltration. Up to 70% of the anemia associated with rheumatoid arthritis may be multifactorial,[106] including iron deficiency.[107,108] Of 184 patients admitted to intensive care units, most patients with anemia were found to have EPO levels and iron study results consistent with ACD; however, 13% also had iron, folate, or vitamin B_{12} deficiency.[109] The role of frequent phlebotomy in hospitalized patients should be fully appreciated[110] (see box on Diagnosis of Anemia of Chronic Diseases).

Anemia of chronic disease may also be undiagnosed in complicated medical patients. For example, the anemia of renal failure traditionally has not been thought of as an ACD but rather as an anemia of absolute EPO deficiency. However, efficient dialysis leads to an improved response to EPO,[111,112] which suggests that other factors, perhaps including cytokines, play a role. Anemic hemodialysis patients may have occult infections of nonfunctioning arteriovenous grafts with markers of inflammation and EPO resistance; removal of these grafts may correct the anemia.[113] Fifty percent of adults with chronic idiopathic neutropenia have an anemia consistent with ACD.[114] Remarkably, multiply traumatized patients have increased inflammatory cytokines and inappropriately low EPO levels consistent with ACD.[22] In patients with congestive heart failure, TNF is elevated, cytokine levels are proportional to the severity of anemia, and EPO level is not elevated in proportion to the degree of anemia, all consistent with ACD playing a role in the anemia commonly found in patients with heart failure.[115-117]

Although the clinical setting in which the anemia is found helps with the diagnosis of ACD, in 30% of cases, no chronic illness can be identified, and acute illnesses can also lead to anemia.[11] The ACD is primarily a diagnosis of exclusion. This may necessitate evaluation of the bone marrow to ensure adequate iron stores; to rule out infiltration by tumor, fibrosis, or infections; and to exclude myelodysplastic syndromes (MDS) (Fig. 35-1). It should be noted, however, that in a study of mostly older patients with an idiopathic mild anemia (10 ± 0.6 g/dL), a bone marrow aspirate with biopsy was found to add little to an extensive negative serologic workup and physical examination.[111]

The diagnosis of ACD usually is made on the basis of elevated bone marrow iron stores (usually assessed by serum ferritin) and low serum iron level, low transferrin level, and low total iron-binding capacity. Because ACD is a hypoproliferative and sometimes microcytic anemia, the differential diagnosis includes iron deficiency. A low serum ferritin level associated with anemia suggests iron deficiency. A normal or elevated ferritin level is more difficult to interpret because ferritin is an acute-phase reactant. Some investigators argue that a ferritin level higher than 50 ng/mL excludes any component of iron deficiency even in inflammatory states. However, a meta-analysis of iron studies in clinical reports from 1842 subjects with serum ferritin levels above 45 ng/mL showed a prevalence of iron deficiency of 6.7%, but 3.5% of 1368 subjects with a serum ferritin level of greater than 100 ng/mL had iron deficiency.[118] Other researchers have shown that in acute inflammation, serum ferritin levels greater than 3500 ng/mL can coexist with absent bone marrow iron stores tested by aspirate.[119] Nomograms correcting ferritin for the degree of inflammation present have been published.[120] In 120 anemic patients with inflammatory, infectious, or malignant diseases in

Diagnosis of Anemia of Chronic Diseases

The diagnosis of ACD is primarily one of exclusion and often is difficult. Various laboratory tests have been suggested, but few have proven value in the general population because ACD occurs in too large a variety of acute and chronic illnesses. The best way to diagnose ACD, at least provisionally, is to document an anemia of underproduction (i.e., low reticulocyte index) with low serum iron and low transferrin levels and an elevated serum ferritin level in the setting of a systemic, usually inflammatory, illness. A thorough search may be necessary to document the precise underlying illness.

Other causes of anemia, such as hemolysis, nutritional deficiency, or sequestration, should be ruled out, and a component of iron deficiency should be strongly considered in a patient with systemic inflammation and a low or "normal" serum ferritin concentration. These other causes of anemia often accompany ACD. Bone marrow examination usually is not essential for the diagnosis but may be necessary to rule out other diagnoses, including malignancy (including MDS), infection, or iron deficiency.

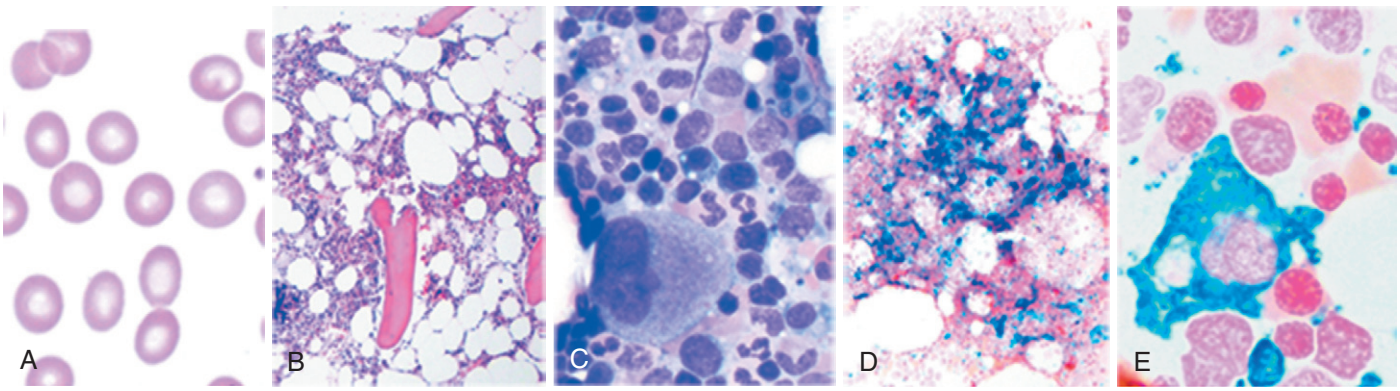

Figure 35-1 ANEMIA OF CHRONIC DISEASE. **A**, Peripheral blood typically exhibits a normochromic, normocytic anemia. **B** and **C,** Bone marrow examination is sometimes performed to rule out other causes of anemia. Typically, the bone marrow is morphologically normal. **D** and **E,** Prussian blue iron stain shows increased iron stores with increased histiocytic iron but decreased sideroblastic iron.

whom bone marrow aspirates were obtained for assessment of iron stores, the serum ferritin level was significantly lower in patients who were iron deficient but was still elevated (63.7 versus 212 ng/mL).[107] A three-step algorithm has been derived for patients with rheumatoid arthritis and serologic evidence of ACD. Male patients with hemoglobin levels less than 11.0 g/dL and serum ferritin concentration less than 40 mg/L have iron deficiency, and those with mean corpuscular volumes greater than 85 fL or an iron saturation level greater than 7% have ACD. This formula led to a correct diagnosis in 89% of patients but has not been independently validated.[108] Most investigators maintain that serum iron studies cannot predictably rule out iron deficiency.[121]

Additional functional tests of iron status have been developed, including soluble transferrin receptors (sTfrs), hemoglobin concentration in reticulocytes (CHr), percent of hypochromic RBCs (% HYPO), and serum hepcidin levels. sTFrs are elevated in iron-deficiency anemia. Several studies have shown that the numbers of transferrin receptors on erythroblasts are lower in rheumatoid arthritis patients with ACD than in patients with iron-deficiency anemia,[34] and some may be decreased even below those without inflammatory conditions.[122] In addition, the levels of sTfr in rheumatoid arthritis and ACD are normal or slighter higher than normal (although generally lower than those with iron-deficiency anemia).[123,124] Patients with rheumatoid arthritis and elevated concentrations of serum transferrin receptors have responded to iron therapy.[124] Algorithms that integrate serum ferritin, sTfr concentration (or a ratio of sTfr to log ferritin, known as an sTfr index), and other markers of inflammation (e.g., ESR or CRP) have been derived in attempts to differentiate iron deficiency from ACD (with or without concomitant iron deficiency).[125-127] A useful strategy, where these tests are available, may be a measured and calculated sTfr index, which reflects iron stores in conventional anemia and in ACD. An sTfr index above 0.8 may discern iron deficiency in subjects with inflammation, and an index above 1.5 may do likewise in subjects without inflammation.[127,128] Recently, the algorithm has been modified to incorporate hepcidin levels, which may increase specificity for iron deficiency in ACD,[129] but this has not yet been prospectively confirmed. Reticulocyte hemoglobin concentration (CHr or Ret he), distinct from indices of mature RBCs, can reflect the recent status of iron stores in normal or EPO-induced erythropoiesis.[130-132] Hepcidin levels, extensively reported based on urinary assays (reported as a hepcidin-to-creatinine ratio), have been shown to mirror hepatic hepcidin mRNA concentrations in patients with a range of inflammatory diseases. A recently developed serum hepcidin immunoassay holds promise.[76] The development of sTfr-, CHr- or Ret he-, and hepcidin-based algorithms for iron-replete and iron-deficient ACD is ongoing.[129] A combination of these newer tests is likely to be useful in diagnosing ACD, but none is fully characterized or yet widely incorporated into clinical practice. Thus, until these assays are reproducibly integrated into clinical care, the diagnosis of ACD remains a clinical one.

TREATMENT

The anemia associated with chronic illness is often mild. In 2120 subjects with rheumatoid arthritis, a classical inflammatory cause of ACD, the annual incidence of anemia less than 10 g/dL, which was proportionate with markers of inflammation, was only 1.5%, with a lifetime prevalence of 13.7%.[35] In 420 subjects with cancer referred for radiation therapy, 16% had Hgb levels of less than 10 g/dL.14 Thus, correction of anemia per se may be unnecessary, especially if contributing factors can be reversed.

There may also be teleologic beneficial contributions of ACD. The fever associated with infections has been shown to inhibit bacterial growth, and decreased iron concentrations (as seen in ACD) act synergistically with pyrexia to inhibit bacterial growth.[133] This attempt by hosts to withhold iron from invaders, called *nutritional immunity,* has been postulated to be an adaptive factor of ACD.[95] Furthermore, elevations in serum iron have been associated with a discernible increase in cancer risk.[6-9] However, ACD can be severe, and almost by definition patients with ACD have comorbidities. Optimizing any reversible process, including hemoglobin and oxygen content and delivery, may have a dramatic beneficial effect because, as discussed, the range of underlying diagnoses in ACD is broad, and therapy precludes a uniform approach. In addition, few randomized, well-controlled, blinded studies are available to support anecdotal therapeutic observations (see box on Treatment of Anemia of Chronic Diseases).

Optimal treatment of ACD is correction of the underlying disease process, if known and if possible. ACD mirrors laboratory[94,106] and clinical[26] correlates of disease activity and duration of disease in rheumatoid arthritis. HIV patients receiving highly active antiretroviral therapy have a mean increase in hemoglobin concentration of more than 3 g/L compared with a decrease in hemoglobin concentration in patients not receiving these medications.[134] Treatment of underlying inflammatory diseases using cytokine antagonists, such as anti–TNF-α therapy, can lead to improvements in anemia.[65-67] Unfortunately, definitive treatment of chronic diseases is the exception.

Serum levels of EPO, although often elevated in ACD, are not elevated appropriately for the degree of anemia. Moreover, inhibition of hematopoiesis by cytokines is reversed in model systems by EPO.[100] Not surprising given the underlying physiology in many cases of ACD, a number of studies have shown responses to EPO, although high doses may be necessary. This strategy may be more cost effective than transfusion. A small, multicenter, placebo-controlled trial monitored the effects of EPO in patients with rheumatoid arthritis and a clinical diagnosis of ACD. The results showed a dose-dependent response to 50 to 150 U/kg of EPO three times each week; 11 of 17 patients had a response rate of almost six hematocrit points.[135] Anemic patients with AIDS who were treated with recombinant EPO had a significantly decreased transfusion requirement, especially if their endogenous EPO level was less than 500 IU/L; however, all of these patients were also receiving zidovudine, a potential bone marrow

Treatment of Anemia of Chronic Diseases

Treating ACD often is unnecessary if the patient is asymptomatic. However, if the anemia is symptomatic or severe, treatment of the anemia itself may be indicated. Epidemiologic studies, such as those in patients with heart failure, HIV, cancer, or kidney disease, suggest physiologic and subjective improvement in signs and symptoms after treatment for anemia.[171,172] However, treatments need to be individualized because the risks of erythropoiesis-stimulating agents or iron therapy in non–iron deficient subjects are theoretically real and practically unknowable given the variety of underlying conditions that are incorporated under the rubric of chronic disease. A trial of ACD-directed therapy may be indicated in symptomatic patients.

The first priority in ACD should be to correct any reversible contributors to the anemia. Because the extent of ACD mirrors the activity of the underlying disease, all efforts should be made to treat the underlying disease. Furthermore, efforts to correct anemia should be modulated by the recognition that the "optimal" target hemoglobin for subjects with ACD is not known. Reports of anemia in subjects without inflammation but religiously opposed to transfusions have suggested a physiologic cutoff for anemia of 5 g/dL, below which increased mortality is seen.[173,174] In addition, acutely ill patients have not been shown to benefit, in randomized, controlled studies, from transfusion "triggers" above 7 g/dL.[174] Nonetheless, symptomatic improvement is seen in subjects with a range of chronic diseases who were treated for anemia of a more modest degree.[171]

Transfusion therapy may be the most common form of treatment of symptomatic ACD, albeit with the potential for transmitting infection; inducing alloimmunization; or, rarely, leading to graft-versus-host disease.

suppressant.[136] Recombinant EPO raised the hemoglobin level in patients with a variety of nonhematologic malignancies, including squamous cell cancer, breast cancer, and colon cancer.[137-140] Large trials enrolling patients undergoing chemotherapy have suggested that once-weekly injections of recombinant EPO are as effective as thrice-weekly injections.[141] Injections of long-lasting EPO analogues have been effective in treating the anemia that occurs with chemotherapy administration[142] and in animal models of ACD[143] and can be used to decrease the frequency of administration.

A starting dose of 20,000 units given subcutaneously each week, anecdotally believed to be a reasonably upper limit in kidney disease patients, can be initiated.[144] If a hemoglobin response is seen, the dose can be decreased and the duration prolonged to titrate the hemoglobin to an asymptomatic level. Careful follow-up and dose titration are essential to minimize expense; the number of injections needed; and, extrapolating from other studies, any potential detriment seen from high hematocrits or high levels of exogenous EPO. This response may take 4 to 8 weeks and should be monitored with objective symptomatic improvements (e.g., exercise tolerance). If after 2 weeks the serum EPO level is higher than 100 mU/mL and the hemoglobin concentration has not increased by at least 0.5 g/dL or if after 2 weeks of treatment the serum ferritin level is higher than 400 ng/mL, a response is very unlikely.[145] In a multivariate analysis of 80 patients with chronic anemia of cancer, only the absolute hemoglobin value, serum EPO level, and ferritin level, but not disease status, bone marrow involvement, or treatment status, were independent predictors of response to EPO treatment.[145] In general, responses by patients with ACD to EPO range from 40% to 80% and can take up to 4 weeks.[135,146,147] Studies suggest that if no effect is seen by 3 months, further treatment is unlikely to be effective.[145]

Functional iron deficiency, even in the setting of normal or elevated total iron stores, is one possible reason for a failed response to EPO.[148] This may be caused by a baseline iron deficiency, depletion of iron stores during hematopoiesis, or an inability to mobilize stored iron; the latter is a hallmark of ACD. Intravenous iron decreased EPO requirements, even compared with oral iron, in several cohorts, including hemodialysis patients[149] and those with inflammatory bowel disease.[150] Intravenous iron improves EPO responses and is a cost-effective measure in dialysis patients, even in those with elevated ferritin levels.[151] In addition, anemia arising from concomitant true EPO deficiency and EPO "resistance" in chronic kidney disease has been successfully managed with supplemental intravenous iron, in short-term studies,[152,153] despite elevated ferritin levels in these subjects. The long-term risks and benefits from such an approach are not known. Paradoxically, iron chelators such as deferoxamine have been shown in some animal studies to have mild effects on ACD, perhaps by decreasing free radicals and inflammation, but other studies have not duplicated this finding.[147,154]

Although EPO administration often leads to an increased hemoglobin concentration, this does not a priori ensure an improvement in morbidity, mortality, or quality of life. Reversal of anemia with EPO in randomized and nonrandomized, open-label studies has been correlated with improvements in functional status, pain, nausea, anxiety, level of activity, and fatigue in large cohorts of patients receiving chemotherapy and smaller studies of cancer patients not undergoing chemotherapy.[137,140,141,155] However, many of these studies have limitations.[115] A thorough examination of the literature led to the suggestion that in cancer patients receiving chemotherapy, the hemoglobin level should be maintained at 12 g/L, and further rigorous studies on the impact on quality of life are necessary.[155] Many studies have shown that pretreatment anemia is a poor prognostic factor for a wide variety of patients with solid tumors undergoing chemotherapy and irradiation, and it is unclear whether correction of this anemia can improve survival.[17]

Most studies and consensus statements on the efficacy of correcting anemia have derived from cancer patients receiving chemotherapy. However, the acute anemia and symptoms associated with myelosuppressive chemotherapy have limited similarities to ACD. Small and preliminary studies of cancer patients with ACD who were not receiving cytotoxic therapy suggest that performance and quality of life may improve with increased hemoglobin concentrations.[140] However, in a large study of critically ill patients, no change in a variety of outcomes were observed when patients were transfused when the hemoglobin level was 10 g/L as opposed to a control group in whom the transfusion trigger was a hemoglobin level of 7 g/L.[156] Although administration of EPO to critically ill patients decreased the number of transfusions, no change in clinical outcome was observed.[157]

Moreover, enthusiasm for EPO use in symptomatic patients with ACD must be tempered by recent observations in individuals with kidney disease and cancer in whom erythropoiesis-stimulating agents (whether short- or long-acting forms of EPO) were associated with increased risks of stroke and thromboembolism, respectively, with a suggestive increase in mortality in large studies.[144,158-163] Studies have also indicated that critically ill patients and those with cancer undergoing chemotherapy may have an increased rate of thromboses and overall death when treated with EPO, particularly if target hemoglobins are higher than 10 to 11 g/dL.[159,163] Increasing the hematocrit to 42% in a large number of hemodialysis patients with cardiac disease led to an increased number of deaths, and the number of cardiac events was increased in patients with chronic renal disease treated with EPO with a goal of complete normalization of hemoglobin (12.0-15.0 g/dL) as opposed to partial normalization (10.5-11.5 g/dL).[164,165] Although low pretreatment hemoglobin levels have been demonstrated repeatedly to be a predictor of good response to chemotherapy and radiation,[166] two studies have demonstrated that patients with breast cancer or head and neck cancer treated with EPO have increased disease progression and worse survival than placebo-treated patients.[167,168] This finding may reflect a direct antiapoptotic effect of EPO on tumors.[169] Not all studies have demonstrated increased risks associated with aggressive EPO treatment in patients with kidney disease or cancer.[159,170] However, based on these studies and interim analyses of several additional studies, in early 2007, the U.S. Food and Drug Administration warned that EPO should be given only in the lowest possible doses necessary to avoid blood transfusions. More recently, consensus agreements have urged that for patients with cancer, erythropoiesis-stimulating agents should only be used in those receiving chemotherapy and only when chemotherapy is with palliative (i.e., not curative) intent.

In summary, although treatment of patients with ACD often increases the hemoglobin level and may improve quality of life and function, data from formal, well-controlled studies are pending, especially for patients not receiving cytotoxic chemotherapy. In particular, high doses of EPO or high hemoglobin levels may be associated with increased risk for cardiac events, thromboses, and tumor progression. Clinicians and patients should be reminded of the unclear benefits and risks in the ACD population of erythropoiesis-stimulating agents and iron. Treatment should be initiated cautiously and followed closely. It is hoped that targeted therapies for ACD, focusing on disrupting cytokine signaling or interfering with hepcidin activity, will be soon available for clinical trials.

SUMMARY AND FUTURE DIRECTIONS

Anemia is common in many chronic inflammatory, infectious, and malignant conditions, and often it is multifactorial. Anemia is exacerbated by inflammatory cytokines, which are thought to be the most important causative factors in ACD. ACD is difficult to diagnose but usually can be strongly suspected based on clinical findings, elimination of other causes of anemia, low serum iron and transferrin levels, and elevated ferritin level. Cytokines such as IFN and TNF have wide-ranging effects, including both direct and indirect inhibition of hematopoiesis. Direct inhibition of hematopoiesis is mediated by both a relative decrease in EPO as well as a decrease in iron available for hemoglobin synthesis. Many of the abnormalities of iron metabolism in ACD are caused by cytokine-induced increases in hepcidin, and appreciation of the role of hepcidin in ACD may aid in the diagnosis and treatment. Anemia, iron deficiency, and hepcidin may have independent antimicrobial and antitumor roles, and this needs further

study. Controlled studies, clearly revealing the impact of correction of anemia on quality of life, medical outcomes, and survival of patients with ACD, particularly in those not undergoing chemotherapy, could provide insight into the role of hypoxia on tumors and other disease. The treatment of patients with ACD should be focused on correcting the underlying disease. Although increasing hemoglobin with exogenous EPO can be quite effective, the potential deleterious results of this strategy must be considered. Development of new agents that might stimulate erythropoiesis but not cancer and risk factors for deleterious EPO effects need to be investigated. In addition, the risk of EPO therapy specifically in the ACD, as opposed to in renal disease or as part of chemotherapy, needs to be investigated.

CHAPTER 36

HEME BIOSYNTHESIS AND ITS DISORDERS: PORPHYRIAS AND SIDEROBLASTIC ANEMIAS

Stephen J. Fuller and James S. Wiley

The porphyrias and the sideroblastic anemias are metabolic disorders that involve defects in heme biosynthesis. Most forms of porphyria are inherited in a mendelian autosomal dominant pattern, but some types are recessive and others are acquired through exposure to porphyrinogenic drugs and chemicals. A linked group of diseases, the porphyrinurias, are not porphyrias but have in common alterations of heme biosynthesis. Porphyrins are tetrapyrroles, which are ubiquitous in nature and exhibit characteristic red fluorescence on exposure to ultraviolet light. The iron-porphyrin complex, called *heme,* is central to all biologic oxidation reactions. In plants, the porphyrin molecule is combined with magnesium to form chlorophyll. Porphyrin biosynthesis is one of the most essential biochemical processes in most life forms.

In humans, mutations affecting the first enzyme of the heme biosynthetic pathway produce sideroblastic anemia. Inborn errors that occur at subsequent sites in this pathway usually result in metabolic disorders known as the *porphyrias* (Fig. 36-1). Historical analysis of the potential presence of acute porphyria in the British royal family has been published,[1-3] as well as a study of the family of Vincent van Gogh.[4]

HEME BIOSYNTHESIS

Biosynthetic Pathways

Heme biosynthesis is an essential pathway and occurs in all metabolically active cells that contain mitochondria. It is most active in erythropoietic tissue, where it is required for hemoglobin synthesis, and in hepatic tissue, where the heme forms the basis of various heme-containing enzymes such as the cytochromes P450, catalase, cytochrome oxidase, and tryptophan pyrrolase. The synthetic pathway starts with the condensation of glycine and succinyl CoA to form 5-aminolevulinate (ALA) under the control of the mitochondrial enzyme ALA synthase (ALAS). This enzyme requires pyridoxal phosphate as a cofactor. A series of enzymes then controls the conversion of ALA first to the monopyrrole porphobilinogen (PBG) and then to the various porphyrins. Iron is inserted into protoporphyrin by the enzyme ferrochelatase to form heme (see Fig. 36-1). During the past 10 years, complementary deoxyribonucleic acid (cDNA) clones have been obtained for all of the enzymes of heme biosynthesis, and the structures of the corresponding genes have been determined. These advances are certain to improve understanding of the pathogenesis of the porphyrias and methods for identification of carriers. The enzymes of the biosynthetic pathway have all been mapped to specific chromosomes (Table 36-1). Heme synthesis and its disorders have been the subject of reviews,[5-10] and advances in our knowledge of mitochondrial iron trafficking and metabolism have recently been reviewed.[11]

Control of Heme Biosynthesis

The overproduction of porphyrins and their precursors in the different porphyrias is mainly hepatic or erythropoietic in origin. In the acute porphyrias and in porphyria cutanea tarda (PCT), the liver is the main source of overproduction; in congenital porphyria, the marrow is the main source; and in erythropoietic protoporphyria, porphyrins are overproduced by the liver and marrow.

Control of hepatic heme biosynthesis is regulated by the rate of the initial enzymatic step, ALAS (now designated ALAS1), which is under negative-feedback control by heme. This occurs by more than one mechanism. Heme represses transcription of the ALAS1 gene and increases the rate of degradation of the messenger ribonucleic acid (mRNA) (Fig. 36-2, *A*). At the posttranslational level, heme blocks the translocation of pre-ALAS1 into the mitochondrion.[12] In the mitochondrion, the molecular mass of ALAS is smaller than that of the cytosolic pre-ALAS[12] because of the removal of the mitochondrial targeting sequence. Finally, heme regulates levels of mature ALAS by activation of a mitochondrial proteolysis system.[13]

The erythroid bone marrow is the major heme-forming tissue in the body, producing 85% of the daily heme requirement. Heme synthesis in erythroid cells varies from that in hepatocytes; it is linked to tissue differentiation, and the half-life of the same end product of the two is quite different. Heme complexed with globin is preserved in circulating red blood cells for approximately 120 days, whereas heme produced in liver for cytochromes and enzymes, such as catalase, is subject to much more rapid turnover, measurable in hours. Regulation in the liver is exquisitely sensitive to fluctuations in intracellular heme levels[14] and responds rapidly to the requirements for synthesis as described in Fig. 36-2, *A.* However, heme synthesis in the bone marrow shows a more leisurely response. This fundamental difference is explained by the finding of two different tissue-specific isoenzymes and two different cDNAs for human liver or "housekeeping" ALAS (ALAS1) and an erythroid ALAS (eALAS or ALAS2), which is expressed exclusively in erythroid cells.[15] The gene for ALAS2 has been mapped to the X chromosome and that for the hepatic enzyme to chromosome 3.[15] The ALAS2 gene has 11 exons; exons 5 to 11 encode the catalytic domain of the enzyme and include a lysine residue that forms a Schiff base with the pyridoxal phosphate cofactor. Exon 1 contributes to the 5′-untranslated region (UTR) whose structure allows iron to regulate ALAS2 mRNA translation, whereas exons 1 and 2 contribute the sequence that targets the enzyme to the mitochondria and is cleaved after import. Succinyl CoA synthetase associates specifically with ALAS2 within the mitochondrion, which helps promote the first step of heme synthesis.[16]

Enzyme levels of ubiquitous and erythroid isoenzymes of ALAS are controlled by different mechanisms. Ubiquitous ALAS1 levels in liver are regulated by negative feedback by heme that inhibits gene transcription and import of pre-ALAS1 (see Fig. 36-2, *A*). More recently ALAS-1 has been shown to be upregulated by peroxisome proliferator-activated receptor-gamma, coactivator 1, alpha (PPAR-γ coactivator 1-α) which regulates mitochondrial biogenesis and oxidative metabolism. Transcription of this coactivator 1-α is controlled by glucose availability. Coactivator 1-α production increases when glucose levels are low, leading to increased levels of ALAS-1 and heme. These conditions are conducive to an acute attack of porphyria. However, the relative contribution of heme and PPAR-γ coactivator 1-α in regulating ALAS-1 expression remains to be resolved.[17,18] In contrast, heme does not affect transcription of the ALAS2 gene, which is under the control of erythroid-specific promoters such as GATA1, a globin transcription factor. Whether heme

inhibits import of pre-ALAS2 into the mitochondrial matrix remains to be unequivocally established. Heme may possibly also prevent the accumulation of intracellular iron by controlling the acquisition of iron from transferrin (see Fig. 36-2, *B*). In addition to transport of iron from plasma to the cytosol by the transferrin receptor, a second transport step is required for mitochondrial uptake of iron. This step is fulfilled by mitoferrin,[19] a member of the solute carrier 25 family of proteins located in the inner mitochondrial membrane, which to import iron into the mitochondrion must interact with the adenosine triphosphate (ATP)-binding cassette transporter ABCB10.[20] Levels of intracellular iron regulate the translation of ALAS2 mRNA. Cellular iron homeostasis is maintained through a posttranscriptional regulatory mechanism, which is mediated by iron regulatory proteins that bind to iron-responsive elements in mRNA of target genes to either increase or decrease translation.[21,22] The RNA binding activity of iron-responsive proteins (IRP) is regulated by mitochondrial iron-sulfur cluster synthesis and cytosolic iron levels.[23-25] When iron is available for heme synthesis, translation of ALAS2 is allowed to proceed as a result of decreased IRP binding to the 5′ UTR IRE of ALAS2 mRNA. In contrast, under iron-depleted conditions increased IRP binding to ALAS2 mRNA blocks translation and ensures that ALAS2 and protoporphyrin levels are not produced in excess of available iron. Furthermore, to prevent the cell from becoming iron deficient, increased translation of mRNA from genes that increase cellular iron, such as the transferrin 1 gene, results from stabilization of mRNA by binding of IRPs to mRNA (see Chapter 33). This effect ensures that protoporphyrin synthesis is coupled to iron availability.

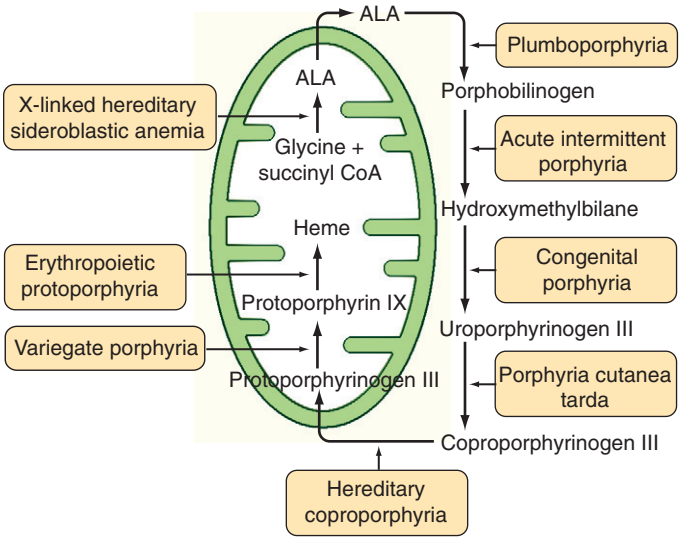

Figure 36-1 PATHWAY OF HEME BIOSYNTHESIS IN MAMMALIAN CELLS. The first step in the pathway is catalyzed by aminolevulinate synthase (ALAS) and occurs within the mitochondrion using pyridoxal 5′-phosphate as a cofactor. 5-Aminolevulinate (ALA) then leaves the mitochondrion and is converted by ALA dehydratase to give a monopyrrole, porphobilinogen. Four molecules of this compound are converted by porphobilinogen deaminase to a linear tetrapyrrole, hydroxymethylbilane. This molecule is then cyclized by uroporphyrinogen III synthase to uroporphyrinogen III, which is decarboxylated to coproporphyrinogen III. This molecule enters the mitochondrion and is oxidized in succession by coproporphyrinogen III oxidase and protoporphyrinogen III oxidase. The product is protoporphyrin IX, a substrate for ferrochelatase, which catalyzes the insertion of Fe^{2+} to form heme. The defective steps associated with specific porphyrias and X-linked hereditary sideroblastic anemias are shown.

A second rate-limiting step in the overall heme synthetic pathway lies at the level of porphobilinogen deaminase (PBGD), which has a low endogenous activity and is inhibited by protoporphyrinogen and coproporphyrinogen. There are also two forms of PBGD. The PBGD gene (HMBS) encodes two enzymes, which arise from alternative splicing of PBGD mRNA. One isoform is expressed in all cells, whereas a second is restricted to red cells.[26] Erythroid PBGD is stimulated by erythropoiesis in vitro and may play a regulatory role in heme biosynthesis during differentiation.[27]

HMBS, the human PBGD gene, has attracted extensive investigation because of the practical importance of detecting carriers of the gene for acute intermittent porphyria.[28] Studies of the genetic locus of PBGD on chromosome 11 show great molecular heterogeneity, with up to 50 mutations resulting either in single amino acid substitutions or premature chain termination listed in the National Center for Biotechnology Information dbSNP database (http://www.ncbi.nlm.nih.gov/snp). Most human mutations have been described in exons 10 and 12,[29] which is consistent with alteration of the binding sites for the dipyrromethane cofactor for the enzyme. The three-dimensional structure of PBGD has been defined by x-ray crystallography, which has allowed study of the structural and functional implications of mutations.[30]

Table 36-1 Porphyrias: Clinical Involvement, Enzymatic Etiology, and Chromosomal Location

Porphyria (Synonym)	Acute Attack, Skin and Organ Involvement	Enzyme of Heme Biosynthesis Affected	Chromosome Location
—	—	Hepatic aminolevulinate synthase-1 (ALAS1)	3p21
X-linked sideroblastic anemia	Bone marrow	Erythroid ALA synthase (ALAS2)	Xp11.21
X-linked dominant protoporphyria	Skin, red cells, liver	Erythroid ALA synthase (ALAS2)	Xp11.21
ALA dehydratase deficiency porphyria (plumboporphyria)	Acute liver	ALA dehydratase (porphobilinogen synthase)	9q33.1
Acute intermittent porphyria (intermittent acute porphyria)	Acute liver	Porphobilinogen deaminase (hydroxymethylbilane synthase)	11q23.3
Congenital erythropoietic porphyria (Günther disease)	Skin, red cells, bone marrow	Uroporphyrinogen III synthase	10q25.2–q26.3
Porphyria cutanea tarda (symptomatic porphyria, cutaneous hepatic porphyria)	Skin, liver	Uroporphyrinogen decarboxylase	1p34
Hereditary coproporphyria	Acute skin, liver	Coproporphyrinogen oxidase	3q12
Variegate porphyria (porphyria variegata)	Acute skin, liver	Protoporphyrinogen oxidase	1q22
Erythropoietic protoporphyria (erythrohepatic protoporphyria)	Skin red cells, liver	Ferrochelatase (heme synthase)	18q21.3

ALA, 5-Aminolevulinate.

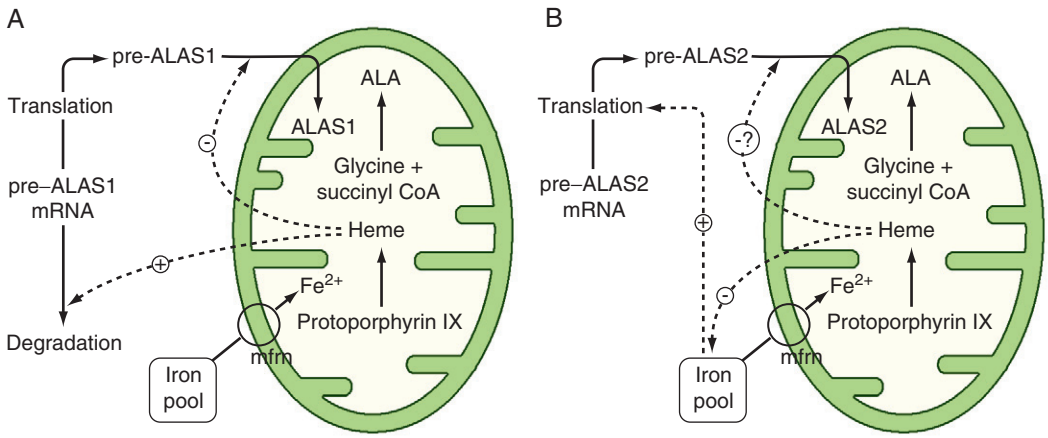

Figure 36-2 A, CONTROL OF HEME SYNTHESIS IN HEPATIC AND OTHER TISSUES. The rate of heme synthesis depends on the first and rate-limiting enzymatic step catalyzed by aminolevulinate synthase-1 (ALAS1). Heme represses transcription of the ALAS1 gene, increases the rate of degradation of its messenger ribonucleic acid (mRNA), and blocks the translocation of the ALAS1 isoenzyme into the mitochondrion. **B,** CONTROL OF HEME SYNTHESIS IN ERYTHROBLASTS. Cytosolic iron enhances the translation of mRNA of the pre-ALAS2 by inhibiting the interaction of a repressor protein with an iron-responsive element in the mRNA. The product of the last step, heme inhibits the uptake of iron from transferrin into the cytosol. Heme also may inhibit translocation of ALAS2 into the mitochondrion. The overall result is that the rate of heme synthesis is tightly linked to the availability of iron for the ferrochelatase reaction. Mitoferrin (mfrn) transports Fe^{2+} into the mitochondrial matrix. *ALA,* 5-Aminolevulinate.

Table 36-2 Classification of Porphyrias

Classification	Disease	Biochemistry	Clinical Features
Acute porphyria	Acute intermittent porphyria	Increased ALA and PBG	Acute attack
	Variegate porphyria	Increased ALA and PBG; increased porphyrin	Acute attack; photosensitivity
	Hereditary coproporphyria	Increased ALA and PBG; increased porphyrin	Acute attack; photosensitivity
	ALA dehydratase deficiency porphyria	Increased ALA; increased porphyrin	Acute and chronic neuropathy
Nonacute porphyria	Porphyria cutanea tarda	Increased porphyrin	Photosensitivity
	Erythropoietic protoporphyria	Increased porphyrin	Photosensitivity
	Congenital porphyria	Increased porphyrin	Photosensitivity
	X-linked dominant protoporphyria	Increased porphyrin	Photosensitivity
Porphyrinurias	Lead, alcohol, iron deficiency anemia, liver disease	Various biochemical manifestations	Various clinical presentations

ALA, 5-Aminolevulinate; *PBG,* porphobilinogen.

PORPHYRIAS

Biologic and Molecular Aspects

The porphyrias are classified as acute or nonacute (cutaneous) according to their clinical and biochemical features (Table 36-2).

Each of the different types of porphyria is linked to a reduced activity or deficiency of a specific enzyme in the heme biosynthetic pathway, with the exception of the recently described X-linked dominant erythropoietic protoporphyria, which results from inheritance of a gain-of-function mutation in the ALAS2 gene[31] (see Fig. 36-1). When porphyria is caused by a loss-of-function mutation, the resulting enzyme deficiency impairs the production of the end-product heme, and there is overproduction and increased excretion of the heme precursors formed by the steps before the enzyme defect. There is also a compensatory increase in activity of the initial and rate-controlling enzyme ALAS. In the acute porphyrias, there is overproduction of all the porphyrins and porphyrin precursors (e.g., ALA, PBG) formed proximal to the enzyme defect. The increased excretion of porphyrin precursors in the acute porphyrias is caused by decreased activity of PBGD in these conditions. The decrease can be caused by genetic mutation of the enzyme (in acute intermittent porphyria) or by inhibition of PBGD by protoporphyrinogen and coproporphyrinogen in variegate porphyria and hereditary coproporphyria, respectively.[32]

In the nonacute porphyrias, there is overproduction of all porphyrins formed before the enzyme defect but no overproduction of porphyrin precursors. The cause of this lack of overproduction of porphyrin precursors in the nonacute porphyrias is unclear, but it may result from a compensatory increase in the activity of the enzyme PBGD in addition to increased activity of ALAS and site-specific heme synthesis.[33] The pattern of overproduction and excretion of porphyrins and porphyrin precursors in the various porphyrias is shown in Table 36-3. A consequence is that each of the different porphyrias is characterized by a different excretion pattern. Quantitative studies of the different porphyrins and precursors in the urine and feces usually identify the particular type of porphyria. The porphyrin precursors ALA and PBG and the more water-soluble porphyrins (with multiple carboxyl groups) are excreted mainly in the urine. Other porphyrins are mainly excreted in the feces by way of the bile (see box on Measurement of Porphyrins and Precursors).

The clinical manifestations of an acute attack of porphyria can be explained by dysfunction of the central, peripheral, and autonomic nervous systems. The mechanism by which altered heme synthesis results in dysfunction is unknown.

Perhaps the most likely hypothesis is that the neurologic and muscular manifestations of acute porphyria arise as a result of heme deficiency within the nerve cells, which causes dysfunction of the energy-dependent Na^+/K^+ ATPase. The proposal that axonal dysfunction results from impaired energy metabolism is supported by the

findings of axonal membrane depolarization during acute attacks of porphyric neuropathy and reduction in inward rectification between episodes.[38] However, this does not exclude the possibility that ALA may also act as a pharmacologic agent in these diseases, compounding the effects of heme deficiency.[39] ALA has a prooxidant effect on rat brain tissues and generates free radical species during its autoxidation, and this oxidant stress has been proposed to directly damage myelination by Schwann cells.[40,41] The concept of autoxidation or oxidative stress is supported by the hypothesis that manganese excess could contribute to induction of superoxide dismutase[42] and increased indicators of such stress in lead exposure.[43] There is evidence that ALA enters cells by a pathway common to it and γ-aminobutyric acid (GABA).[44]

Measurement of Porphyrins and Precursors

Fluorescence of urine under ultraviolet (UV) light is recommended as the initial screening test for the acute porphyrias,[34] whereas plasma fluorescent spectroscopy is the best initial test for diagnosis of cutaneous porphyrias.[35] Diverse techniques such as high-pressure liquid chromatography,[36] quantitative extraction, and various forms of fluorometry are used to measure porphyrins and precursors.[37] The International Federation of Clinical Chemistry and Laboratory Medicine presents diagnostic information on the Internet (www.ifcc.org).

Genetic Aspects

The enzymatic links and genetic loci in each of the hereditary porphyrias are shown in Table 36-1. Nearly all are inherited as autosomal dominant traits. The Chester porphyria family pedigree (Fig. 36-3) shows autosomal dominant inheritance of acute porphyria with attacks of neurovisceral dysfunction without cutaneous hypersensitivity. This was originally reported as a dual porphyria[45]; however, identification of a heterozygous truncating mutation in the HMBS gene and no mutations in other heme biosynthesis enzymes in affected individuals has confirmed that Chester porphyria is a variant of acute intermittent porphyria.[46] Few carriers of the abnormal gene show clinical signs of the disease, but most can be identified by intensive biochemical investigation. The rare congenital porphyria shows autosomal recessive inheritance. The mutations producing each of the acute porphyrias are heterogeneous at the molecular level and include complete or partial gene deletions, alterations of splicing or stability of mRNA, and missense mutations. An exception is variegate porphyria in South Africa, in which the founder effect ensures a predominance of the Arg59Tryp mutation in protoporphyrinogen

Table 36-3 Changes in Porphyrins and Their Precursors in the Porphyrias, Porphyrinurias, and Hereditary Sideroblastic Anemia

Porphyrias and Other Conditions	ALA	PBG	Urine Uroporphyrin	Urine Coproporphyrin	Feces Coproporphyrin	Feces Protoporphyrin	Erythrocyte Protoporphyrin
ACUTE PORPHYRIAS

ALA, 5-Aminolevulinic acid; *PBG*, porphobilinogen.
**PBG* may cyclize to uroporphyrin nonenzymatically.

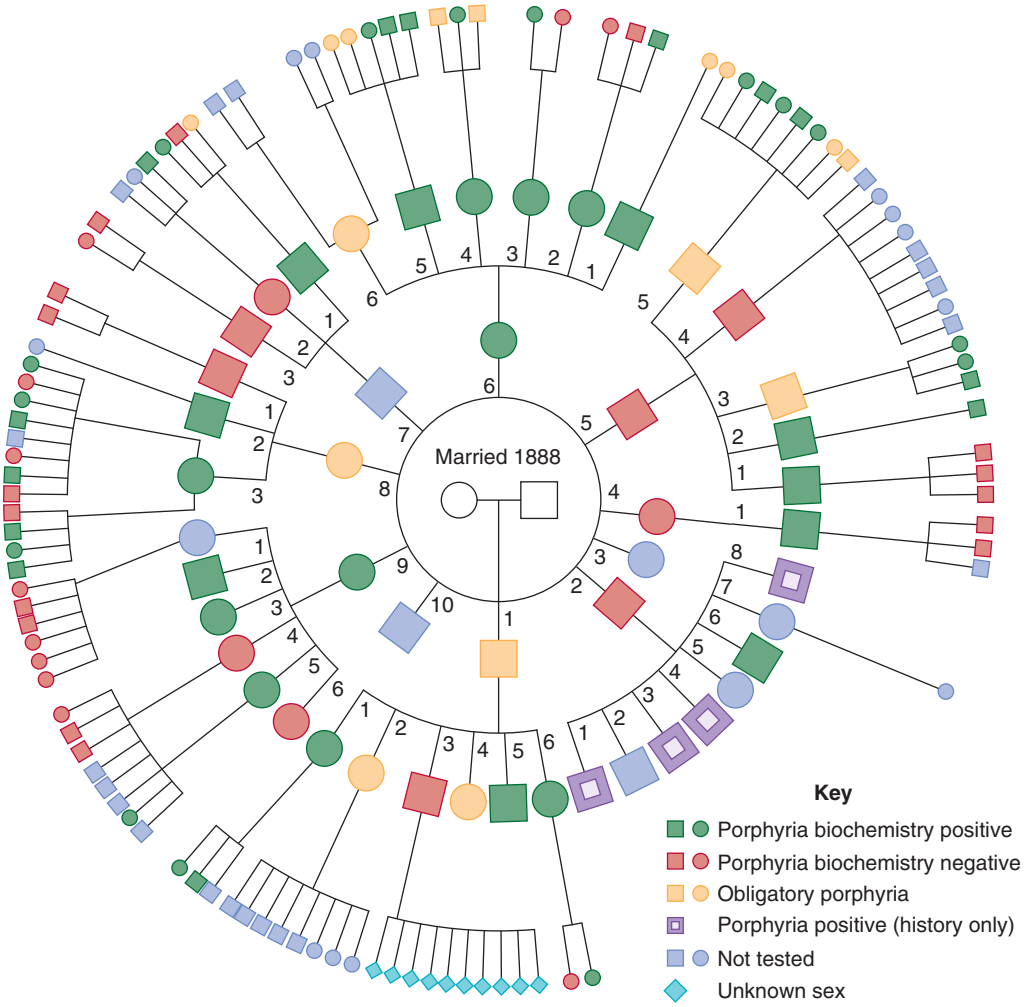

Figure 36-3 THE CHESTER FAMILY PEDIGREE. The propositus, Peter Dobson, was a salmon fisherman from a close-knit community living on the bank of the River Dee, which runs through the city of Chester, UK. Most of the 330 descendants of his marriage in 1888 still live in the city. Many suffered disabling illnesses and psychiatric upsets, which often went unrecognized as porphyria. The family called their illness *Dobson's complaint*. Chester porphyria has recently been confirmed as a variant of acute intermittent porphyria. *(Courtesy Giles R. Youngs.)*

oxidase.[47,48] Homozygotic or compound heterozygotic inheritance has been found in a number of the porphyrias, as has concurrent inheritance of more than one defect. This may present as two types of porphyria in one family[49] or as two types in one patient.[50,51] Dual porphyrias most commonly arise from a combined deficiency of uroporphyrinogen decarboxylase with PBGD, coproporphyrinogen oxidase, or protoporphyrinogen oxidase.[52]

The prevalence of the different forms varies widely. For example, in northern Europe and North America, approximately 1 of 10,000 individuals carries the gene for acute intermittent porphyria, although only about 10% of the affected persons will present with clinical features. It has been suggested that spontaneous mutation accounts for 3% of acute intermittent porphyria cases.[53] Variegate porphyria occurs in 1 of 400 white South Africans. There is a reduction in gene frequency in variegate porphyria from generation to generation that suggests that the allele associated with it is selectively deleterious.[54] The same is probably true of the other porphyrias.

Acute Intermittent Porphyria

Clinical and Laboratory Manifestations

Acute intermittent porphyria is the most severe of the acute porphyrias. During an attack, patients display abdominal and neuropsychiatric or neurovisceral disturbances. Onset occurs in puberty; female patients exhibit a fourfold greater incidence of attacks than males. Attacks occur mainly in young adults and become less frequent after menopause. It is uncommon to see attacks in children.[55] Crises may vary in duration from several days to months. They are most commonly followed by complete remission, although deaths are still reported, especially with acute intermittent porphyria[56] (see box on Precipitating Factors in Acute Porphyria).

Gastrointestinal symptoms occur in 95% of cases; most patients present with acute colicky central abdominal pain. Examination reveals tenderness but little rigidity, and patients may also experience limb pain or generalized muscular aches. Severe vomiting may occur, and constipation is usual. Hyponatremia occurs in severe attacks.

Motor neuropathy complicates two-thirds of porphyric attacks and may be the presenting feature. Motor involvement is most common, but paresthesias may also occur. Paralysis usually starts peripherally and then spreads proximally; however, in some patients, shoulder girdle involvement may be the first manifestation. The neuropathy may progress rapidly, resulting in respiratory insufficiency. Weakness, usually symmetric, involves proximal and distal limb muscles more often than those of the trunk. Upper limbs and proximal muscles are often affected. Involvement of the wrists, ankles, and small muscles of the hand may lead to a permanent deformity (Fig. 36-4), and trunk muscle weakness can lead to respiratory embarrassment. Death is usually caused by respiratory paralysis.

Precipitating Factors in Acute Porphyria

Most patients who have inherited acute porphyria enjoy normal health and go through life without any knowledge of their disorder or ever experiencing an acute attack. All porphyric patients, however, are at risk for developing an attack if exposed to various precipitating factors. Drugs are the most common precipitating agents. Other factors that may trigger attacks include alcohol ingestion, reduced caloric intake (from fasting or dieting), and infection. Smoking can cause more frequent attacks.

Hormonal status is also important. Attacks are more common in females, and they rarely occur before puberty or after menopause. Pregnancy and oral contraceptives may also precipitate attacks. Some women experience regular attacks, commencing in the week before the onset of menstruation. These may require luteinizing hormone–releasing hormone (LH-RH) antagonists for control (Table 36-4).

Drugs for Porphyria

Before prescribing any medication to a porphyric patient, advice must be sought from an appropriate specialist. Full drug lists are available on the Internet (www.drugs-porphyria.org). It should be borne in mind that such lists are far from encyclopedic, that new drugs are constantly being introduced to the pharmacopoeia, and that any form of combined preparation must be viewed with suspicion, because little is known about metabolic interactions in these diseases.[57] More details of such use and side effects of drugs can be sought from the literature.[58]

Figure 36-4 BILATERAL WRISTDROP CAUSED BY PERIPHERAL NEUROPATHY IN A PATIENT WITH ACUTE INTERMITTENT PORPHYRIA.

Progressive weakening of the voice may suggest this; treatment requires tracheotomy and intermittent positive pressure ventilation. Paresthesias, numbness, and objective evidence of sensory impairment may occur with loss of pinprick sensation, which is most marked around the shoulder and hip areas; generalized tonic-clonic seizures occasionally occur.

Severe anxiety, depression, and frank psychosis are the main psychiatric manifestations of porphyric attacks. These psychiatric manifestations may result in a patient being misdiagnosed as suffering from a primary psychiatric disorder. Agitation, mania, depression, hallucinations, and schizophrenic-like behavior may occur. Psychiatric manifestations may persist between attacks.[59] Quality of life is severely affected in those suffering from repeated attacks of acute porphyria.[60]

The cardiovascular system is involved in approximately 70% of attacks. Sinus tachycardia (to 160 beats/min) and hypertension can occur; these elevations usually revert to normal after an attack. There is evidence that hypertension may occasionally be permanent, even in latent cases of acute intermittent porphyria (see box on Differential Diagnosis of Acute Intermittent Porphyria).

Differential Diagnosis of Acute Intermittent Porphyria

Attacks of acute porphyria must be distinguished from other causes of acute abdominal pain or peripheral neuropathy sometimes associated with psychosis.[61] Heavy metal poisoning (i.e., lead or arsenic) and Guillain-Barré syndrome must be considered, as well as paroxysmal nocturnal hemoglobinuria with its characteristic early morning hemoglobinuria and abdominal pain.[61]

During an attack, all patients excrete a massive excess of the porphyrin precursors, 5-aminolevulinic acid (ALA) and porphobilinogen (PBG), in their urine. Urine, when first voided, is clear and darkens on exposure to light as the hexa-hydroporphyrins, the porphyrinogens, are oxidized to porphyrins.

A rapid screening test during an acute attack is to mix equal volumes of urine and Ehrlich aldehyde reagent and observe for the pink color of porphobilinogen; alternatively the urine can be left standing in sunlight to observe darkening in color. The differential diagnosis of porphyrias uses qualitative and quantitative measurement of porphyrins and precursors, with subsequent use of enzymatic assay and identification of familial genetic alterations.[62]

Table 36-4 Precipitating Factors in Acute Porphyria

Drugs	Other Stimuli

Sulfonamides	
Sulfonylureas	

Other Acute Porphyrias

Hereditary Coproporphyria

Hereditary coproporphyria combines the clinical features of acute porphyria with photosensitive skin manifestations. It results from mutations in the gene encoding coproporphyrinogen oxidase, whose activity is decreased,[63,64] leading to overproduction of coproporphyrin.

The porphyrin precursors ALA and PBG and the more water-soluble porphyrins (with multiple carboxyl groups) are excreted mainly in the urine. Other porphyrins are mainly excreted in the feces by way of bile.

Figure 36-5 CUTANEOUS LESIONS AND SCARRING IN A PATIENT WITH VARIEGATE PORPHYRIA.

Variegate Porphyria

Variegate porphyria is similar to hereditary coproporphyria, except that there are more severe skin lesions, sometimes with scarring (Fig. 36-5). Protoporphyrinogen oxidase is the affected enzyme, and protoporphyrin is the major circulating porphyrin. Conventionally, variegate porphyria is most readily diagnosed by measurement of fecal porphyrin concentrations. However, it has been reported[65] that biliary porphyrin levels may provide a better discriminator from normal patients in the asymptomatic phase. As in erythropoietic protoporphyria, there is a tendency toward cholelithiasis. The mechanism by which gallstones form is not certain, but some studies have suggested that porphyrins are cholestatic.[66] In hereditary coproporphyria and variegate porphyria, the pathway intermediates produced in excess, coproporphyrinogen and protoporphyrinogen, respectively, are inhibitors of the secondary rate-controlling enzyme PBGD.[32,67] Numerous mutations in the protoporphyrinogen oxidase gene have been described leading to 50% reduction in enzyme activity. In a few cases, homozygosity or compound heterozygosity has been described.[68,69]

ALA Dehydratase–Deficiency Porphyria

In this porphyria (also known as plumboporphyria), the ALA dehydratase activity is depressed, as occurs in lead poisoning. The clinical picture resembles acute intermittent porphyria, but very few cases have been described, and the disease only manifests in homozygous cases when there is a precipitating factor.[70,71]

Concurrent Porphyrias

The concurrent porphyrias are a rare group of conditions in which there is concurrent inheritance of two different defects within the heme biosynthetic pathway. There is good precedent for more than one defect within the pathway. Previous descriptions[50-52] have shown the presence of concurrent porphyria within a family, and toxicologically there is good evidence that exposure to poisons such as lead can induce multiple changes within the pathway.[72] The first reported example of concurrent porphyria in a family combined the clinical features of acute and cutaneous porphyria, and biochemical analysis confirmed the segregation of variegate porphyria and PCT as independent inherited traits.[73] In another patient, dual genetic defects involving ALA dehydratase and coproporphyrinogen oxidase have been described[51] (see box on Management of Acute Porphyria).

Management of Acute Porphyria

Treatment of Acute Attack

A carbohydrate intake of 1500 to 2000 kcal/24 hr should be maintained throughout the attack to reduce porphyrin synthesis; give this orally or, for more severe attacks, through a fine-bore Teflon nasogastric tube. If this cannot be tolerated, intravenous dextrose (e.g., 20% solution, 2 L/day) should be given. If early in the attack (2 to 4 days from onset), give intravenous hematin as heme arginate (Normosang, Orphan Europe) at 2 to 4 mg/kg over 30 minutes once or twice each day to further reduce the overproduction of porphyrin and precursors.[74,75] Hematin (Panhematin, Lundbeck) in similar doses may also be used, although it should be reconstituted in human albumin solution to avoid phlebitis and mild transient prolongation of coagulation times. No renal complications have occurred with the standard recommended dosages, and even patients with renal insufficiency tolerate hematin well, although the dosage should be reduced slightly. The action of heme therapy may be extended by heme oxygenase blockers such as tin protoporphyrin.[74] Liver transplantation may be an effective treatment for life-threatening acute intermittent porphyria that fails to respond to medical therapy.[76]

Prophylaxis

Many drugs are contraindicated, and the patient must be warned to avoid precipitating factors. Alcohol should be restricted and smoking discouraged. Dieting (<800 kcal/day) must be avoided. Pregnancy should also be avoided if the disease is active. If a patient requires an anesthetic, nitrous oxide, ether, and cyclopropane are safe, and suxamethonium appears to be a safe muscle relaxant. The opiates and belladonna derivatives can be used for premedication and propofol for maintenance of anesthesia. Infection can precipitate an attack and should therefore be sought and treated. Blood relatives of patients should be screened to see if they carry the gene.

Luteinizing hormone-releasing hormone (LH-RH) antagonists that suppress ovulation are a valuable form of prophylaxis in menstrually related attacks.[77] Estrogens and progestogens such as those in the contraceptive pill must be avoided in acute porphyria. The same applies to most steroids and receptor antagonists such as mifepristone.[78]

Nonacute or Cutaneous Porphyrias

In all cutaneous porphyrias, porphyrins (which are photosensitizing) are deposited in the upper layers of the skin, and they are responsible for the characteristic skin lesions.[79] In the development of these lesions, reactive oxygen species and other radicals are formed and probably induce oxidative membrane damage, particularly to mast cells, which enables complement activation as one part of the inflammatory reaction[80] (see box on Management of Nonacute Porphyria).

Porphyria Cutanea Tarda or Cutaneous Hepatic Porphyria

Biologic and Molecular Aspects

PCT exists in inherited and acquired forms. An inherited, more severe form of this disease, hepatoerythropoietic porphyria (HEP), has been described.[85] Mutations in the uroporphyrinogen decarboxylase are found in around one-third of patients with PCT. In inherited and acquired forms, there is diminution in the activity of hepatic uroporphyrinogen decarboxylase, which converts uroporphyrinogen to coproporphyrinogen by the stepwise decarboxylation of the acetyl

Management of Nonacute Porphyria

Patients should avoid exposure to sunlight and use sunblock and physical barriers such as cotton gloves.

Porphyria Cutanea Tarda

The clinical features are reversed by removing any precipitating agent such as alcohol, halogenated hydrocarbons, and drugs. The patient should be screened for hepatic neoplasm and hepatitis C infection. The mainstay of treatment is to remove liver iron by venesection of 500 mL of blood weekly until clinical remission occurs or until the hemoglobin level falls below 12 g/dL. Chloroquine, at low doses of 125 mg twice per week for several months, has also been helpful because it enhances urinary clearance of porphyrin. When this is not possible, oral cimetidine has been used.[81] When venesection is difficult, parenteral and orally active iron chelators can be used to reduce liver iron stores. It is of value to screen the patient and first-degree relatives for hereditary hemochromatosis.

Erythropoietic Protoporphyria

Oral β-carotene offers effective protection in erythropoietic porphyria (EPP) against solar sensitivity. It does so by quenching the radical formation that is a feature of the skin damage. Yellowing of the skin (i.e., carotenemia) is one side effect. Interruption of the enterohepatic protoporphyrin circulation by bile salt–sequestering agents such as cholestyramine reduces plasma protoporphyrin levels and may retard the development of the liver disease. Liver transplantation has been reported to be an effective measure in preventing the progression of this disease.[82]

Congenital Porphyria

Erythropoiesis should be reduced by means of erythrocyte hypertransfusion and by hematin or heme arginate infusion.[83] Bone marrow transplantation has given encouraging biochemical and clinical results, but insufficient numbers of patients have been treated to be certain of the future prospects of this therapy.[84] Splenectomy and chloroquine therapy (125 mg twice weekly) have an ameliorating effect, as does hypertransfusion, but life expectancy is usually severely shortened.

groups to methyl groups. The mechanism of enzyme inhibition has recently been elucidated, whereby iron-dependent oxidation of uroporphyrinogen generates uroporphomethene, a competitive inhibitor of uroporphyrinogen decarboxylase.[86] Most carriers of mutant uroporphyrinogen decarboxylase are not clinically evident unless precipitating factors are present. Iron alone or chlorinated hydrocarbons can diminish activity of uroporphyrinogen decarboxylase, and this effect is greatly potentiated when both are given together.[87,88] In a murine model, precipitation of uroporphyria by chlorinated hydrocarbons is dependent on hepatic cytochrome P450 1A2 oxidase activity, and inherited variations in enzyme function may modulate susceptibility to PCT in humans.[87]

Patients may have clinical and biochemical evidence of liver disease. Hepatic siderosis invariably occurs, and iron is one of the causative agents in acquired PCT. An association of PCT with hereditary hemochromatosis has been documented, with about 20% of PCT patients being homozygous for the Cys282Tyr mutation in the HFE gene, a defect that characterizes hereditary hemochromatosis.[89-91] These results strongly implicate the HFE gene as a genetic susceptibility factor in acquired PCT. An association between PCT and hepatitis C infection is well documented, and in countries with high prevalence rates, hepatitis C virus may be the dominant risk factor.[92] An apparent association has emerged between human immunodeficiency virus (HIV) infection and PCT.[93] It is possible that therapy for HIV with zidovudine precipitates the disease, but it is more likely that the association is merely coincidental or that the viral infection unmasks the preexisting uroporphyrinogen decarboxylase defect.[94]

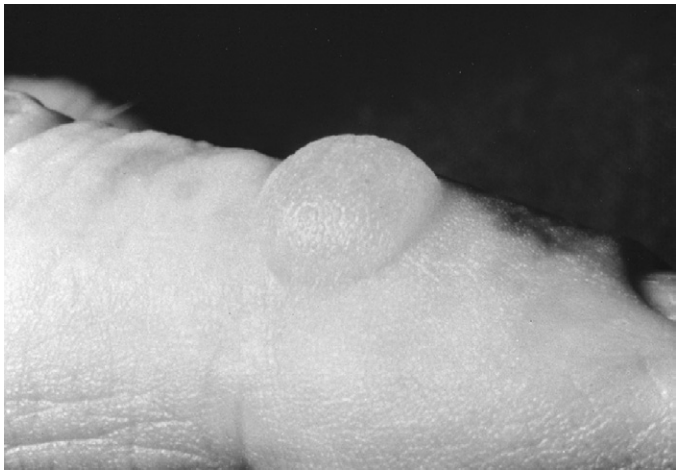

Figure 36-6 A BULLOUS SKIN LESION OF PORPHYRIA CUTANEA TARDA.

Genetics

Whereas familial PCT is inherited in an autosomal dominant mode, HEP is inherited in an autosomal recessive pattern.[95] As in the other genetic lesions in the porphyrias, there is heterogeneity in the mutations causing PCT and HEP phenotypes.[96,97] In the inherited form, more than 40 different mutations (mainly missense) have been identified in uroporphyrinogen decarboxylase, many of which lie near the dimer interface resulting in an unstable protein and reduced enzyme activity.[98] In different population groups, it is difficult to find the relative numbers of acquired and familial disease. In one analysis in Hungary, 77.5% of patients were found to suffer from the acquired form, and of the patients with the familial disease, females were affected more than males, suggesting that inheritance may predispose patients to estrogen-precipitated disease.[99]

Clinical Features

The most striking clinical feature of both forms of PCT is a bullous dermatosis on light-exposed areas. This starts as erythema and progresses to vesicles that become confluent to form bullae (Fig. 36-6), which may hemorrhage and leave scars; pruritus is often troublesome. Milia are common and may precede or follow vesicle formation. Facial hypertrichosis is common and may serve as a diagnostic clue. In less severe cases, increased fragility of the skin may be the only clinical sign. In severe cases, photomutilation can result, usually because of infection of slowly healing lesions.

The thickening and scarring with calcification has been described as pseudoscleroderma. Hyperpigmentation is common, and women often complain of hirsutism. Neurologic change is not observed. Patients may have clinical and biochemical evidence of chronic liver disease, sometimes with cirrhosis. There is an association with hepatocellular carcinoma. Hepatomegaly is particularly common when alcohol intake is excessive.

Precipitating Factors

Many patients with PCT have multiple precipitating factors, including mutations of the HFE gene, hepatitis C infection, or exposure to estrogen.[89,90] Excessive alcohol intake is an important precipitating agent, perhaps because of increased hepatic iron deposition in alcoholics. However, certain halogenated hydrocarbons are sometimes implicated. PCT may also develop in people treated with hemodialysis for kidney failure. An outbreak of cutaneous hepatic porphyria in southeast Turkey in 1956 was traced to seed wheat dressed with the

fungicide hexachlorobenzene. A neoplastic subgroup has been identified in which PCT is associated with benign or malignant liver tumors.

Differential Diagnosis

Other causes of bullous or vesicular skin lesions should be excluded, such as a drug reaction (see box on Pseudoporphyria and Renal Dialysis) or chronic renal failure. The distinction between PCT, variegate porphyria, and hereditary coproporphyria rests on biochemical testing of urine and feces, with the highest levels of urinary uroporphyrin found during attacks of PCT (see Table 36-3).

Erythropoietic Protoporphyria

Biologic and Molecular Aspects

Although not described until 1961, this form of erythropoietic porphyria (EPP), also known as erythrohepatic protoporphyria, is much more common than congenital porphyria. Ferrochelatase activity is reduced in peripheral blood, liver, bone marrow, and skin, and protoporphyrin is synthesized in excess.[103] The erythroid progenitor cells (i.e., burst-forming units-erythroid [BFU-E]) in EPP patients show intense fluorescence when viewed under 405-nm light. The gene mutation in EPP shows heterogeneity as in other porphyrias.[104] The last enzyme of the biosynthetic pathway, ferrochelatase, is important because its endogenous activity is relatively low, and it could act as a control point in the pathway. Ferrochelatase ligates iron bound to three cysteine residues in an iron-sulfur cluster,[105] the mutation of which leads to decreased enzyme activity.[106] A multiple-enzyme complex spanning the mitochondrial membrane would allow for channeling of substrate from the cytoplasm to the mitochondrial matrix.[107] Immunologic studies on human protoporphyria show that immunologically reactive ferrochelatase is present, but that enzyme activity in three subjects was on average only 17% of normal.[108] Gain-of-function mutations in the ALAS2 gene have recently been described that result in increased erythrocyte protoporphyrin despite normal ferrochelatase activity. This newly described, X-linked dominant erythropoietic protoporphyria, leads to accumulation of protoporphyrin in amounts sufficient to cause photosensitivity and hepatic damage.[31]

Pseudoporphyria and Renal Dialysis

The term *pseudoporphyria* has been used to describe a bullous dermatosis associated with a number of dermatologic conditions that bear some resemblance to porphyria.[100] This photosensitivity is often induced by drugs such as the tetracyclines, naproxen, furosemide, voriconazole, oxaprozin, and many others. In these conditions, there is no alteration in porphyrin metabolism or excretion. It is therefore incorrect to name any of them porphyria; the term *pseudoporphyria* should not be applied to them, but only to conditions in which alterations of porphyrin metabolism can be found, such as the bullous dermatosis of hemodialysis.[99]

Patients with renal failure can present with many biochemical features of porphyria before hemodialysis. These abnormalities normalize after dialysis, especially when electrolyte abnormalities such as zinc deficiency are also corrected.[101] In a considerable proportion of patients with chronic renal failure, skin changes resembling porphyria cutanea tarda (PCT) develop some months to years after the onset of maintenance hemodialysis. In a minor proportion, genuine PCT can be diagnosed.[102] In such cases, there are elevated total porphyrin levels in plasma and in urine if the patient is not anuric. These patients present a therapeutic dilemma because they are normally anemic and unsuitable for phlebotomy therapy.

Genetics

EPP is inherited as an autosomal dominant disorder with incomplete penetrance, although recessive inheritance has been described.[109,110] Haplotype segregation analysis has shown intronic nucleotide polymorphisms in the ferrochelatase gene (FECH) that produces aberrant splicing of mRNA to a form that degrades more rapidly, resulting in enzyme deficiency.[111] Although these disease-associated polymorphisms are common,[112,113] there is heterogeneity of the molecular defect, including aberrant splicing and loss of function of the mitoferrin protein.[16,103,104,114]

Clinical Features

The clinical features are mainly cutaneous on exposure to sunlight and can occur at any age, including infancy and childhood.[109] They include pruritic urticarial swelling and redness of the skin on exposure to sunlight. The most distressing symptom is an unbearable burning sensation on the affected parts. Remarkably, such features are ameliorated during pregnancy, which has been linked to lowered protoporphyrin levels.[115] Hepatic involvement, which occurs in later life, involves deposition of hepatotoxic protoporphyrin in the liver and can lead to fatal liver failure from an active chronic hepatitis with cirrhosis.[116] Such protoporphyrin deposition may also cause cholelithiasis; the gallstones contain high concentrations of protoporphyrin. The liver disease of EPP seems to correlate with erythrocyte protoporphyrin concentrations.[117] Mild microcytic anemia has been reported,[118,119] as well as mitochondrial iron accumulation and ring sideroblasts, in about 30% of patients.[120] Late onset of EPP has been reported in patients with myelodysplastic syndrome or overlap myelodysplasia/myeloproliferation. In one patient, EPP has been acquired as a result of expansion of hemopoietic cells containing only one allele of the FECH gene.[121] Inactivation of one allele by deletion involving chromosome 18 thus appears to be sufficient for overproduction of protoporphyrin.[120,122]

Differential Diagnosis

EPP should be distinguished from other causes of a photosensitive rash. The distinction can be made by demonstrating fluorescence in a proportion of red cells (i.e., fluorocytes) in the peripheral blood and confirmed by measurement of greatly increased erythrocyte and fecal protoporphyrin. Patients with EPP have a relatively high incidence of ring sideroblasts in the marrow.[120] This can lead to diagnostic difficulty because some patients with idiopathic sideroblastic anemia have increased levels of erythrocyte protoporphyrin.[123-126] However, EPP can be distinguished by the autosomal dominant inheritance pattern, dermal photosensitivity, normal or low serum levels of iron, and levels of protoporphyrin in red blood cells and feces.

Congenital Porphyria (Günther Disease)

Biologic and Molecular Aspects

Congenital porphyria, or Günther disease, although extremely rare, was the first porphyria to be described in 1874.[127] Unlike the other porphyrias, it is inherited in a mendelian autosomal recessive pattern causing reduced activity of uroporphyrinogen III synthase. The onset of solar photosensitivity results from gross overproduction of porphyrins, caused by deficiency of uroporphyrinogen III synthase. Like other porphyrias, the defective enzyme results mainly from point mutations at multiple sites within the gene.[128] Other enzymes are

largely normal, although there is an increase in ALAS activity,[129] which in some cases has been shown to result from gain-of-function mutations in the ALAS2 gene.[130] Excess porphyrins, particularly uroporphyrin-1, accumulate in the normoblasts of the bone marrow and are excreted in the urine and feces. They are also deposited in bones and in the teeth, resulting in a pink-brown discoloration that fluoresces bright red in light of wavelengths around 400 nm. Dental restoration has been used to correct the esthetic appearance of the teeth. There are frequently profound changes in bone structure in patients with congenital porphyria. This has been linked to vitamin D deficiency because of light avoidance.[131] However, bone changes can be seen when vitamin D levels are adequate, and it is reasonable to speculate that the porphyrins deposited in bone are cytotoxic because similar bone changes are features of homozygous variegate porphyria and HEP.[132]

Clinical Features

Typically the onset of congenital porphyria is from birth, but occasionally late-onset cases have been reported.[133] The skin reaction is severe and can be devastating, and the teeth become brownish pink because of their high porphyrin content. Severe cutaneous photosensitivity is manifested by blistering of light-exposed areas and fragility of the epidermis. Skin thickening occurs, and there is extensive scarring and hypertrichosis. The recurrent damage associated with scarring on the hand may produce a claw-shaped deformity and loss of digits. Dystrophic nails may curl up and drop off. Lenticular scarring may lead to blindness. Hemolytic anemia often occurs and is associated with increased erythrocyte fragility and splenomegaly. Dyserythropoiesis may contribute to the anemia.[134] One patient who underwent splenectomy at 5 years of age has been described with needle-like inclusions of porphyrin in the circulating red cells (Fig. 36-7).[135]

Differential Diagnosis

The most characteristic feature of congenital porphyria is the excess production of series 1 porphyrins rather than series 3 isomer produced in the other porphyrias. Red blood cells fluoresce in ultraviolet light, as do the brown-stained teeth, because of high porphyrin content (see box on Pseudoporphyria and Renal Dialysis).

SIDEROBLASTIC ANEMIAS

Sideroblastic anemias are a heterogeneous group of disorders characterized by anemia of varying severity and diagnosed by finding ring sideroblasts in the bone marrow aspirate. The peripheral blood shows hypochromic red cells, which are microcytic in the hereditary forms (Fig. 36-8, *A*) but are often macrocytic in the acquired forms of the disease. The red blood cell parameters from automated cell counting may show bimodal volume distribution curves or widened range of cell sizes (see Fig. 36-8, *B*); however, this dimorphic size distribution is not always present. Tiny inclusions may be visible in the red blood cells; these can be confirmed as iron-containing Pappenheimer bodies by Prussian blue staining of the blood smear (see Fig. 36-8, *C*). The diagnostic test is bone marrow examination together with Prussian blue staining of the bone marrow smears.

The presence of ring sideroblasts (see Fig. 36-8, *D*) is defined as erythroblasts containing iron-positive (siderotic) granules arranged in a perinuclear collar distribution around one-third or more of the nucleus. Electron microscopic examination has shown that these siderotic granules are mitochondria containing amorphous deposits of ferric phosphate and ferric hydroxide. Iron is also bound to mitochondrial ferritin, a molecular form of ferritin that can be distinguished from cytoplasmic ferritin and that accumulates in large amounts in the erythroblasts of subjects with impaired heme synthesis.[136,137]

A dimorphic size distribution is evident. **C,** Peripheral blood showing Pappenheimer bodies (Prussian blue stain). **D,** The bone marrow smear stained with Prussian blue shows ring sideroblasts.

Iron overload is a common clinical feature of refractory sideroblastic anemia and, in severe cases, may lead to complications that characterize secondary hemosiderosis (e.g., diabetes, cardiac failure). Marrow examination shows prominent erythroid hyperplasia, which is a sign of the ineffective erythropoiesis and is responsible for increased iron absorption. The sideroblastic anemias have diverse causes but have in common an impaired biosynthesis of heme in the erythroid cells of the marrow. Most sideroblastic anemias are acquired as a clonal disorder of erythropoiesis, with various degrees of myelodysplastic features (Table 36-5). The inherited forms are uncommon and occur predominantly in males with an X-linked pattern of inheritance. A number of drugs have been associated with reversible sideroblastic anemia, and ring sideroblasts may be found in patients who abuse alcohol (see Table 36-5). The first descriptions of ring sideroblasts in association with chronic refractory anemias appeared in the late 1950s,[138,139] after an earlier description of familial X-linked hypochromic microcytic anemia.[140]

Hereditary Sideroblastic Anemia

X-Linked Sideroblastic Anemia

Biologic and Molecular Aspects

Erythroid cells from patients with X-linked forms of hereditary sideroblastic anemia generally exhibit low activity of ALAS[27,141]; however, for a minority of ALAS2 mutations this effect may be difficult to detect in vitro.[142] A defect in this enzyme is firmly established in patients whose anemia responds to pyridoxine therapy, because pyridoxal phosphate is an essential cofactor for ALAS. However, even affected female patients with moderate anemia unresponsive to pyridoxine have been documented to have low levels of ALAS in bone marrow lysates. In some male patients with X-linked pyridoxine-responsive sideroblastic anemia, the low ALAS activity in bone marrow increased to levels above the normal range when the patient took pyridoxine supplements and recovered from the anemia.[143] There are several possible explanations for this enhancement of ALAS activity by dietary pyridoxine supplements. The most likely is that pyridoxine (or its phosphate) may stabilize the ALAS during folding of the mutant enzyme after its synthesis.[141] The gene for the ALAS2 isoenzyme has been localized to the X chromosome, and this gene is known to be the site of most mutations giving rise to X-linked pyridoxine-responsive sideroblastic anemia.[9,144] Approximately three dozen different mutations have been identified in individuals or families with hereditary sideroblastic anemia, and nearly all have resulted from single base alterations in DNA. A frequent mutation affects arginine at residue 452 of ALAS2, which occurs in a quarter of all pedigrees but does not affect enzyme activity measured in vitro.[145] All known mutations lie between exons 5 and 11 of ALAS2, the region that codes for the catalytic domain, with most lying within exon 9, which contains the lysine at which binding of pyridoxal 5′-phosphate occurs.[7] A mutation, Asp190Val, has been described in a pyridoxine-refractory patient and appears to affect the proteolytic processing of the ALAS2 during or after import into the mitochondrion.[146] The variety of different mutations in the erythroid ALAS2 gene responsible for X-linked sideroblastic anemia and their pyridoxine responsiveness have been reviewed recently.[9]

Table 36-5 Classification of Sideroblastic Anemias

HEREDITARY (NONSYNDROMIC)
X-linked
Autosomal dominant or recessive
ACQUIRED
Idiopathic acquired* (refractory anemia with ring sideroblasts)
Associated with previous chemotherapy, irradiation, or in transition myelodysplasia or myeloproliferative diseases
DRUGS
Alcohol
Isoniazid
Chloramphenicol
Other drugs
RARE CAUSES
Erythropoietic protoporphyria
Copper deficiency or zinc overload
Hypothermia
HEREDITARY (SYNDROMIC)
X-linked sideroblastic anemia with ring sideroblasts and cerebellar ataxia
Myopathy, lactic acidosis and sideroblastic anemia
Pearson syndrome
Thiamine-responsive megaloblastic anemia

*Trial of pyridoxine indicated.

Genetic Aspects

In most families with hereditary sideroblastic anemia, males are affected with an X-linked pattern of inheritance (Fig. 36-9). However, female carriers, although usually normal, can develop erythrocyte dimorphism or varying degrees of anemia. The assignment of the gene for erythroid ALAS2 to the X chromosome[144] and the many mutations documented in erythroid ALAS2 provide the genetic basis for this X-linked disease. In several families, coinheritance of other X-linked traits (e.g., glucose-6-phosphate dehydrogenase [G6PD] deficiency, ataxia with sideroblastic anemia) has been described.[147,148] Sporadic and familial cases have been described that affect only females, which has been shown to represent skewed X-chromosome inactivation ("unfortunate skewing") affecting the normal allele for the ALAS2 gene.[149] The absence of affected male members in these pedigrees suggests that the ALAS2 defects identified are lethal in hemizygous males.

Clinical and Laboratory Evaluation

Typically the anemia of X-linked sideroblastic anemia manifests in infancy or childhood, but the milder forms of anemia may not be found until midlife. Even elderly patients have been diagnosed with this anemia.[150] Some cases may be discovered only during family surveys, which should always be undertaken when hereditary

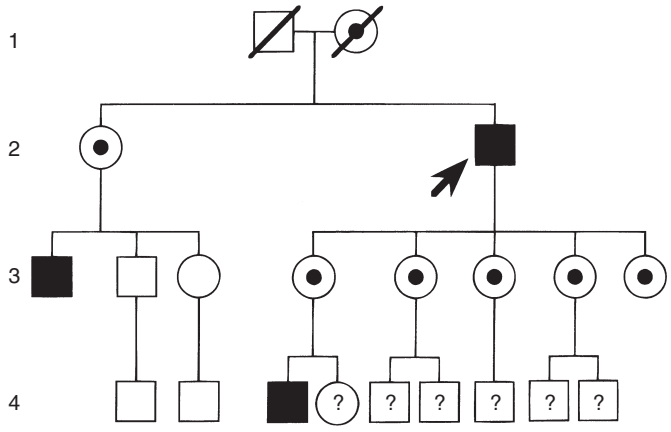

Figure 36-9 PEDIGREE OF A FAMILY WITH PYRIDOXINE-RESPONSIVE SIDEROBLASTIC ANEMIA SHOWING X-LINKED RECESSIVE INHERITANCE. Affected *(filled box),* carrier *(filled circle within open circle),* and unknown status *(question mark within circle or box)* are indicated. Diagonal lines indicate deceased members. This pedigree[143] has been abbreviated to show only the affected branches of the family. The *arrow* indicates the proband.

sideroblastic anemia is diagnosed. Still other patients may present with features of iron overload, such as diabetes or cardiac failure. Iron overload occurs commonly even with mild anemia and may occasionally be seen with female carriers. Enlargement of the liver and spleen may occur with mild abnormalities of liver function tests.

Anemia is extremely variable, but even when little or no anemia is present, the mean corpuscular volume (MCV) is low, and the red cell volume distribution width may be increased. When anemia is severe, the MCV may be as low as 50 fL (50 μm^3). The blood smear shows a population of cells with hypochromic, microcytic morphology (see Fig. 36-8), which contrasts with the other normochromic, normocytic cells (i.e., dimorphism). Anisocytosis, poikilocytosis, elongated cells, and siderocytes may also be seen. The characteristic erythrocyte dimorphism is most prominent in patients with milder anemia, in female carriers, and in patients in whom pyridoxine has corrected the anemia but not restored the MCV to normal. In some pedigrees with only affected females, macrocytosis may be present, which contrasts with the typical microcytosis of male hemizygotes.[126,149] Leukocyte values are normal, whereas the platelet count is normal or increased.

Serum iron concentration is increased, and transferrin shows an increased percentage of saturation with iron. Serum ferritin levels are invariably increased. Ineffective erythropoiesis can be confirmed by ferrokinetic measurements showing that plasma iron clearance is rapid, with subnormal retention of the iron isotope in erythrocytes after 10 to 14 days. Other features of ineffective erythropoiesis may be variably present: a mild increase in bilirubin concentration, decrease in haptoglobin levels, mild increase in lactate dehydrogenase levels, and normal or slight increase in reticulocyte numbers. The magnitude of iron overload correlates poorly with the degree of anemia in patients who are not transfused. The degree of ineffective erythropoiesis is a better predictor of the amount of iron overload. When ferrokinetics are unavailable, the extent of erythroid hyperplasia relative to normal acts as a rough measure of the magnitude of ineffective erythropoiesis. Several studies have shown that the relative increase in erythroid activity multiplied by the patient's age shows a good correlation with the degree of iron overload as measured by plasma ferritin.[151,152] The iron overload does not result from mutations in the HFE gene[153] (see box on Therapy for Hereditary Sideroblastic Anemia).

Differential Diagnosis

Hereditary sideroblastic anemia should be distinguished from idiopathic hemochromatosis, because both have biochemical evidence of iron overload and a similar tissue pattern of iron deposition. Careful hematologic assessment of patient and family members should make the distinction, because the hemoglobin level and MCV are normal in idiopathic hemochromatosis.

Other Nonsyndromic and Syndromic Hereditary Sideroblastic Anemias

X-linked sideroblastic anemia is considered the most common inherited sideroblastic anemia; however, a number of rare forms have recently been identified. These consist of two nonsyndromic sideroblastic anemias, which have a similar phenotype to X-linked sideroblastic anemia, and four syndromic forms where heme synthesis is affected in a variety of other tissues in addition to red cells.

Of the nonsyndromic forms, inherited mutations in both the SLC25A38 and GLRX5 genes have been identified to cause an autosomal recessive pyridoxine-refractory sideroblastic anemia.[156,157] SLC25A38 is located on chromosome 3p22.1 and encodes a mitochondrial carrier protein that may function to import glycine into the mitochondrion or exchange glycine for 5-aminolevulinic acid.[156] Homozygous or compound heterozygote mutations in SLC25A38 result in a similar phenotype to that seen in X-linked sideroblastic anemia, with onset in infancy of a severe microcytic anemia that is refractory to treatment with pyridoxine and folic acid. GLRX5 encodes a mitochondrial protein, glutaredoxin 5, which when deleted in the zebrafish mutant shiraz results in defective iron-sulfur cluster assembly and blocked synthesis of heme.[158] A late-onset pyridoxine-refractory sideroblastic anemia caused by homozygous mutation in GLRX5 has been described in a patient who in middle age developed symptoms of a microcytic hypochromic anemia, type 2 diabetes, cirrhosis, and liver iron overload.[157]

Therapy for Hereditary Sideroblastic Anemia

A trial of pyridoxine (100 to 200 mg/day taken orally) is indicated for 3 months for all patients with hereditary sideroblastic anemia. Response is variable and ranges from complete correction of hemoglobin levels to no effect. Even when pyridoxine completely corrects the anemia (Fig. 36-10), the increase in mean corpuscular volume (MCV) may not reach normal values, and a population of hypochromic, microcytic cells remains.

About 25% to 50% of patients with hereditary sideroblastic anemia show a full or partial response to pyridoxine, and this vitamin should be continued on a lifelong basis in the responders. A lower maintenance dose should be determined for each responding patient by progressive dose reduction, because long-term therapy with pyridoxine at 100 to 200 mg/day has been associated with peripheral neuropathy.[154] The adult nutritional requirement for pyridoxine is 1 to 2 mg/day; some patients have been maintained on as little as 4 mg/day as a supplement.[143] Folic acid supplements should also be administered because the erythroid hyperplasia increases demand for this vitamin.

There is one report of successful allogeneic peripheral blood stem cell transplantation in a 19-year-old man with transfusion-dependent hereditary sideroblastic anemia.[155] Transfusions are the mainstay of treatment for severe anemia unresponsive to pyridoxine. Regular administration of packed red cells using white blood cell filters are given to relieve symptoms and permit normal childhood development. Iron overload and secondary hemosiderosis rapidly progress after transfusions begin; chelation therapy with desferrioxamine or oral deferasirox should be initiated from the onset.

Iron removal may be of great benefit for patients who have mild or moderate anemia and evidence of iron overload.[151,152] These patients can often tolerate intermittent phlebotomy, which is preferable to chelation therapy for iron removal, and should be continued to reduce ferritin levels to less than 300 ng/mL. All patients with iron overload should avoid ingestion of ascorbic acid supplements, which enhance iron absorption and increase the tissue toxicity of elemental iron. Alcohol should also be avoided. Splenectomy is contraindicated in this disease.

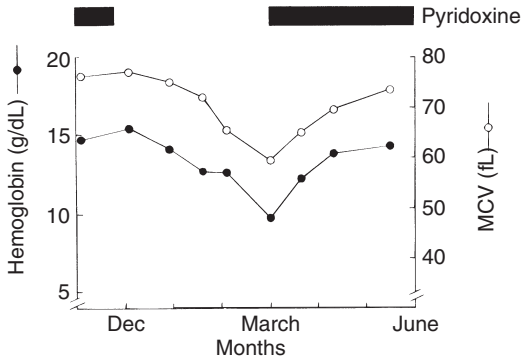

Figure 36-10 RESPONSE OF THE HEMOGLOBIN CONCENTRATION AND MEAN CORPUSCULAR VOLUME (MCV) TO WITHDRAWAL AND REINSTITUTION OF PYRIDOXINE IN A PATIENT WITH RESPONSIVE HEREDITARY SIDEROBLASTIC ANEMIA.

In addition to genetically defined forms of hereditary sideroblastic anemia, four syndromic types have been described, which present with anemia in combination with either muscle, neurologic, or pancreatic tissue involvement. The first of these disorders to be defined by molecular genetics, the Pearson syndrome, is a rare entity that manifests in early infancy with anemia and exocrine pancreatic dysfunction. The anemia is normocytic or macrocytic, reticulocyte counts are low, and variable degrees of neutropenia and thrombocytopenia are present. The bone marrow shows striking vacuolation and ringed sideroblasts.[159] Although usually fatal, milder forms of the anemia are consistent with survival into adult life. The syndrome, which is related to the Kearns-Sayre syndrome, results from deletions, mutations, or duplications of mitochondrial DNA, variably affecting multiple tissues of the body.[160,161]

A second syndromic congenital sideroblastic anemia, X-linked sideroblastic anemia with cerebellar ataxia (XLSA/A), is a rare mitochondrial disease caused by loss-of-function mutations in the ATP-binding cassette transporter ABCB7.[162-164] ABCB7 is localized to the inner mitochondrial membrane and has been proposed to function as an exporter of mitochondrial iron-sulfur clusters to the cytoplasm[165]; however, a direct role in heme synthesis may arise through an interaction with ferrochelatase.[166] Males affected with XLSA/A usually present in infancy with nonprogressive or slowly progressive ataxia and incoordination, which is accompanied by a mild to moderate hypochromic microcytic anemia and the presence of ring sideroblasts on bone marrow examination.

Mutations in the high-affinity thiamine transporter gene SLC19A2, located at 1q24.2, cause the thiamine-responsive megaloblastic anemia (TRMA) syndrome.[167] TRMA has the unusual bone marrow feature of megaloblastic erythroid maturation with ring sideroblasts. TRMA presents with early-onset megaloblastic anemia, diabetes mellitus, and sensorineural deafness, which respond variably to thiamine treatment.

Most recently the genetic variants that cause a fourth syndromic hereditary sideroblastic anemia, myopathy, lactic acidosis, and sideroblastic anemia (MLASA), have been reported.[168,169] A missense mutation in the PUS1 gene coding for pseudouridine synthase-1 causes the rare autosomal recessive disease, MLASA.[168,170] Mitochondrial and cytoplasmic transfer RNAs (tRNAs) from affected patients lack tRNA pseudouridylation at sites normally modified by PUS1; however, the mechanism by which this affects oxidative phosphorylation and iron metabolism in skeletal muscle and bone marrow are yet to be elucidated.[170] MLSA displays genetic heterogeneity such that an identical phenotype is caused by a homozygous mutation in the mitochondrial tyrosyl-tRNA synthetase gene, YARS2.[169] The homozygous mutation in YARS2, identified in three patients from two consanguineous Lebanese families, causes defective mitochondrial synthesis and, similar to mutations in PUS1, results in defective oxidative phosphorylation.[169] MLASA1 and MLASA2 usually present with progressive exercise intolerance commencing in childhood followed by later development of sideroblastic anemia, basal lactic acidemia, and mitochondrial myopathy.

Acquired Sideroblastic Anemia

Acquired sideroblastic anemia is categorized within the myelodysplastic syndromes and may appear de novo or occur after chemotherapy or irradiation (see Table 36-5). The clonal nature of hemopoiesis in this condition was first suggested by Dacie et al.[139] Nearly all cases show evidence of dyserythropoiesis in the marrow, and there may also be dysplastic changes in the myeloid precursors or megakaryocytes, or both. Acquired idiopathic sideroblastic anemia falls within the diagnostic category of refractory anemia with ring sideroblasts as defined by the French-American-British group and World Health Organization classification.[171,172] Acquired sideroblastic anemia has also been a rare finding in myeloproliferative disorders such as idiopathic myelofibrosis or essential thrombocythemia. Distinguishing between idiopathic myelofibrosis and myelodysplasia is sometimes difficult, and there is increasing recognition for an overlap or transitional entity, myelodysplasia/myeloproliferative disease, unclassifiable.[172-174] Thus many patients with refractory anemia with ring sideroblasts and thrombocytosis have a point mutation in the Janus kinase 2 gene (changing valine-617 to phenylalanine), which is a feature usually associated with the myeloproliferative disorders.[175] This latter group have a clinical phenotype that includes normal MCV, marrow fibrosis, and splenomegaly (see Chapter 59).[175]

Biologic and Molecular Aspects

Clonal hematopoiesis has been demonstrated in acquired idiopathic sideroblastic anemia and in the related myelodysplastic syndromes. Specific evidence was first provided by finding a single G6PD isoenzyme in erythrocytes, granulocytes, platelets, and B lymphocytes in a woman who was heterozygous for G6PD and carried two isoenzymes in her skin and T lymphocytes.[176] This technique is applicable only to the few women who have G6PD heterozygosity, but restriction fragment length polymorphism analysis can be applied to most women using probes directed at other X-chromosome genes such as that for phosphoglycerate kinase or to an X-linked, variable-copy-number tandem repeat sequence (see Chapter 1).[177] The results show uniform monoclonality of hematopoiesis in acquired sideroblastic anemia with or without associated myelodysplastic features. Some indirect evidence exists for a primary mitochondrial lesion, perhaps in the mitochondrial respiratory chain, which impairs the reduction of Fe^{3+} because Fe^{2+} is essential for heme synthesis.[178-180] Recurrent mutations in the SF3B1 gene have recently been described in acquired sideroblastic anemia and are found in 65% of patients with refractory anemia and ring sideroblasts.[181] The product of SF3B1 is associated with mRNA splicing, and mutations in this gene may influence a number of mitochondrial gene networks resulting in iron-laden mitochondria during erythroid development.

Etiology

Clonal chromosomal changes are found in bone marrow cells in approximately 60% of patients with acquired sideroblastic anemia. Characteristic changes are monosomy 7; trisomy 8; deletions involving chromosomes 5, 7, 11, or 20; and a number of balanced translocations.[182] When sideroblastic anemia is acquired after chemotherapy or irradiation, chromosomal changes are usually found and tend to be multiple.[182] Among these changes, the loss of an entire chromosome (5 or 7, or both), deletion of a long arm [del(5), del(7), or del(13)], and an unbalanced translocation are typical.[183,184] When karyotype shows loss of material from chromosomes 5 or 7, or both, a detailed occupational history may show exposure to potentially mutagenic chemical agents in a proportion of patients.[185] However, the development of visible chromosomal changes is probably a late event in acquired sideroblastic anemia and may be preceded by the expansion of a clone of genetically unstable stem cells. This concept is in accord with the view that multiple genetic events underlie the pathogenesis of other myelodysplastic syndromes and acute myeloid leukemia[176,186] (see box on Clinical and Laboratory Evaluation of Sideroblastic Anemia).

Differential Diagnosis

Ring sideroblasts are not limited to acquired sideroblastic anemia; they also occur in other myelodysplastic conditions, such as refractory anemia with excess blasts, in which the blast count is higher than 5%.[195] Careful examination of peripheral blood and bone marrow can distinguish acquired idiopathic sideroblastic anemia from these related myelodysplastic conditions. Family surveys are very useful in distinguishing acquired from hereditary forms of sideroblastic anemia, because the latter may present in late adult life.

Clinical and Laboratory Evaluation of Sideroblastic Anemia

Typically, sideroblastic anemia develops insidiously in a middle-aged or elderly patient with normal or increased mean corpuscular volume (MCV) and a blood smear showing a population of hypochromic red cells. Hepatosplenomegaly may be present. Leukocyte and platelet counts are usually normal, but some patients have thrombocytosis that occasionally exceeds 1000×10^9/L.[187] If leukopenia or thrombocytopenia is present, a careful search should be made for myelodysplastic features, which lead to the more descriptive term of *refractory cytopenia* for the condition.[188,189] An iron stain of the bone marrow aspirate shows ring sideroblasts, which should total more than 15% of all erythroblasts to make the diagnosis of acquired sideroblastic anemia.[171,189-191] Iron cannot be assessed in the marrow trephine biopsy core because it may leach out during decalcification.

The bone marrow also shows erythroid hyperplasia. Although mild dyserythropoiesis (e.g., multinuclearity, nuclear budding) and megaloblastoid changes are present, myelopoiesis and megakaryopoiesis are usually normal. When changes are confined to dyserythropoiesis, the condition has been called *pure sideroblastic anemia*.[189,192] However, dysplasia of myelopoietic and megakaryopoietic elements may be present (i.e., trilineage dysplasia) with the following features: Pelger-Huët–like anomaly, hypersegmentation or hypogranularity of neutrophils, micromegakaryocytes, large mononuclear megakaryocytes, and megakaryocytes with multiple small nuclei (see Chapter 59).[189] Dysmegakaryopoiesis is more easily detected in trephine biopsies than in marrow smears, although the trephine may also show unsuspected islands of myeloblasts characteristic of myelodysplasia.[193] The overall blast count in marrow smears is, by definition, less than 5%, and the peripheral blood monocyte count is less than 1.0×10^9/L. Cytogenetic analysis of marrow aspirates provides important information, because a normal karyotype predicts long survival in any type of acquired sideroblastic anemia.[194]

Prognosis

Acquired idiopathic sideroblastic anemia and the related entity of refractory anemia have the most favorable outlook among the myelodysplastic syndromes, with a median survival of 42 to 76 months and 3% to 12% incidence of leukemic progression in different series.[182,196,197] The prognosis can be correlated with three factors. First is the severity of the anemia, because repeated transfusions markedly increase iron overload and invariably lead to the organ dysfunction characteristic of secondary hemosiderosis (e.g., heart and liver failure, diabetes). The second factor is whether neutropenia and thrombocytopenia are associated with the anemia. These cytopenias form the basis of a simple prognostic scoring system in which two or more of the following place the patient in a poor prognostic category: hemoglobin level less than 10 g/dL, neutrophil count less than 2.5×10^9/L, platelet count less than 100×10^9/L, and blasts more than 5% of the total.[196,197] Thirdly, karyotypic analysis of marrow aspirates provides valuable information, because a normal karyotype carries a more favorable prognosis. Conversely, monosomy 7 or a partial loss of the long arm of chromosome 7 as a single defect imparts a high probability of transformation to acute myeloid leukemia. Multiple chromosomal abnormalities and del(20q) are also associated with an increased risk for progression to leukemia; in contrast, trisomy 8 has no adverse prognostic significance.[182] Evolution of acquired idiopathic sideroblastic anemia to other myelodysplastic conditions, such as refractory anemia with excess blasts, has been described[198] (see box on Therapy for Acquired Sideroblastic Anemia).

Therapy for Acquired Sideroblastic Anemia

Transfusions are indicated for relief of symptomatic anemia. A trial of pyridoxine at 100 to 200 mg/day for 3 months is worthwhile in patients who have anemia but who do not display neutropenia or thrombocytopenia. However, few patients with acquired idiopathic sideroblastic anemia respond to this vitamin. If any response is achieved, maintenance therapy with pyridoxine at lower dosage is indicated. Cyclosporin (5 to 6 mg/kg/day) has been reported to benefit the anemia of the closely related myelodysplastic condition of refractory anemia, although the response appeared limited to those with hypoplastic bone marrows.[199]

SIDEROBLASTIC ANEMIA AND PORPHYRINURIA CAUSED BY DRUGS

Alcohol

Ring sideroblasts may be found in the bone marrow of malnourished anemic alcoholics, usually in the presence of associated folate deficiency.[200-202] In contrast, binge drinking or chronic alcohol ingestion in subjects with good nutrition is not associated with sideroblastic abnormality. Sideroblastic change is never the sole cause for the anemia of alcoholism. Alcohol has a direct toxic effect on hematopoiesis.[203] An increased or high-normal MCV and vacuolation of red blood cell precursors is often seen in addition to the ring sideroblast abnormality. Red blood cells show dimorphic morphology; evidence in the marrow of folate deficiency is present in half of cases.[203] Transferrin saturation and marrow iron stores tend to be increased but may be low if gastrointestinal bleeding is present. The ring sideroblasts gradually disappear over 4 to 12 days when alcohol is withdrawn[202]; during this period, there may be a rebound erythroid hyperplasia, reticulocytosis, and thrombocytosis. Folic acid should be given for the associated megaloblastic changes after blood is taken for vitamin B_{12} and folate assays.

Alcohol consumption lowers the plasma concentration of pyridoxal phosphate, a cofactor for ALAS, needed in the first step in heme synthesis.[204] Conversion of ethanol to acetaldehyde is necessary for this effect, and acetaldehyde acts by accelerating the degradation of intracellular pyridoxal phosphate in the liver, lowering plasma levels of this coenzyme.[205]

Chronic alcoholics have an altered heme metabolism with increased urinary excretion of coproporphyrin, mainly isomer III, but normal urinary excretion of uroporphyrin, ALA, and porphobilinogen. Acute and chronic ethanol ingestion markedly depresses the activity of ALA dehydratase in peripheral blood. Ethanol administration to normal subjects results in increased activity of leukocyte ALAS and erythrocyte PBGD, the two rate-controlling enzymes of the pathway. The activities of each of the other four enzymes are depressed. Ferrochelatase, the enzyme that inserts iron into protoporphyrin to form heme, shows the most marked depression, and in alcoholism there is prolonged depression of uroporphyrinogen decarboxylase, which provides a rationale for the role of ethanol in the etiology of PCT.[206,207] As earlier, ethanol is a major precipitating factor in acute porphyria.[208]

Isoniazid

Administration of the antituberculous drug isoniazid occasionally has been associated with development of a sideroblastic anemia after 1 to 10 months of therapy. The anemia is hypochromic and microcytic, with a dimorphic blood smear and ring sideroblasts in the marrow. This complication is thought to occur only in slow acetylators of isoniazid, allowing this drug to react nonenzymatically with pyridoxal and to form a hydrazone that is rapidly excreted in the urine. The anemia can be fully reversed by coadministration of pyridoxine (25

to 50 mg/day) with isoniazid or by withdrawing isoniazid.[209] Another antituberculous drug, pyrazinamide, may also cause a sideroblastic anemia, which is caused by inhibition of ALAS2 and responds to pyridoxine therapy.[210]

Chloramphenicol

Chloramphenicol is an antibiotic that produces a reversible suppression of erythropoiesis after several days of therapy (plasma levels of 10 to 15 mcg/mL). This effect is predictable and separate from the rare idiosyncratic side effect of aplastic anemia in approximately 1 of 20,000 exposed persons. Nearly all patients given chloramphenicol (>2 g/day) develop vacuolation of the erythroid precursors and ring sideroblasts. These effects are thought to arise from suppression of mitochondrial respiration. Chloramphenicol inhibits mitochondrial protein synthesis and reduces cytochrome *a, a_3,* and *b* levels.[211] Serum iron concentrations are increased, and reticulocyte numbers are subnormal; these changes revert on stopping the antibiotic.

Other Drugs

A reversible acquired sideroblastic anemia has been described with penicillamine therapy and with the use of triethylene tetramine hydrochloride, a copper-chelating agent used in the treatment of Wilson disease.[212] Acquired sideroblastic anemia has also been precipitated by progesterone given to a patient on two separate occasions 15 years apart, and this anemia promptly reversed on withdrawal of the drug.[213]

PRESENTATIONS ASSOCIATED WITH SIDEROBLASTIC ANEMIA OR PORPHYRINURIA

Copper Deficiency or Zinc Overload

The copper content of a Western diet averages 0.9 to 1.6 mg each day, which is only a few times greater than the amount needed to maintain homeostasis of this essential element.[214] Copper deficiency has been described in malnourished premature infants,[215] in patients receiving long-term parenteral or enteral hyperalimentation,[216] after gastrectomy,[217] with copper-chelating agents,[212] or on an idiopathic basis.[218] The syndrome of copper deficiency consists of sideroblastic anemia with hypochromic cells in the blood smear, accompanied by ring sideroblasts and vacuolated erythroid and myeloid precursors in the marrow, and of neutropenia with an absence of late myeloid forms in the marrow (Fig. 36-11). In some reports, patients present with neurologic symptoms such as paresthesias, weakness, or ataxia; and demyelination is seen on the magnetic resonance image of the brain.[218] In infants, additional features may be seen, such as osteoporosis and long bone changes, depigmentation of skin and hair, and central nervous system abnormalities. The platelet counts remain normal. Serum copper and ceruloplasmin levels are low, whereas serum iron and transferrin saturation levels are normal. The serum zinc concentration may be increased.[218] Prompt reversal of the hematologic changes follows therapy with 2 to 5 mg/day of copper sulfate taken orally or 100 to 500 mcg/day of copper supplement to the intravenous alimentation formula.

Large quantities of ingested zinc interfere with copper absorption and produce the neutropenia and sideroblastic anemia characteristic of copper deficiency.[219] Zinc sulfate is freely available from health food stores, and as little as 450 mg/day for 2 years is sufficient for this effect. Sideroblastic anemia has also been ascribed to zinc toxicity arising from the ingestion of coins over a period of many years.[220] Serum zinc levels are high, whereas serum copper and ceruloplasmin levels are low. Zinc must be discontinued for 9 to 12 weeks for full reversal of the anemia and neutropenia.

Iron Deficiency Anemia

In iron deficiency anemia, there is an accumulation of protoporphyrin in erythrocytes that rarely reaches the level found in EPP. The zinc complex of protoporphyrin is produced because ferrochelatase uses Zn^{2+} during iron-deficient erythropoiesis.[221] Erythrocyte protoporphyrin may be raised before changes appear in peripheral blood and may be helpful in diagnosing iron deficiency when serum iron and ferritin levels are rising as a result of patients having started iron therapy. In iron-deficient erythropoiesis, erythroid ALAS activity is reduced below normal.[222]

Hypothermia

Thrombocytopenia, erythroid hypoplasia, and ring sideroblasts have been described in patients with hypothermia associated with neurologic disease.[223] These changes reverse slowly as body temperature returns to normal.

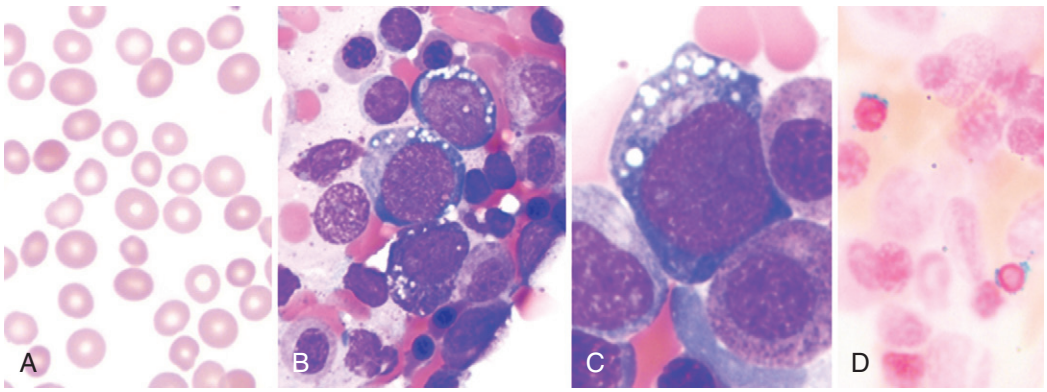

Figure 36-11 THIS 70-YEAR-OLD MAN WAS BEING TREATED WITH ZINC SUPPLEMENTATION AND WAS FOUND TO HAVE ANEMIA AND NEUTROPENIA (HEMOGLOBIN, 8.3 G/DL; HEMATOCRIT, 23.9%; AND WHITE BLOOD CELL COUNT, 1200/μL). His peripheral smear **(A)** showed a biphasic erythroid population with some small slightly hypochromic cells and increased anisocytosis (red blood cell distribution width [RDW], 23.9%). The bone marrow aspirate showed a left shift in granulopoiesis with vacuolization of immature granulocytic and erythroid precursors (**B** and **C**). A Prussian blue–stained aspirate revealed ring sideroblasts **(D).** The patient's copper level was less than 0.1 mcg/mL (normal reference range, 0.75 to 1.45 mcg/mL).

Other Conditions

In hereditary tyrosinemia, excess urinary ALA is excreted because ALA dehydratase is inhibited by succinyl acetone. Like acute porphyria and lead poisoning, this disease is associated with neurobehavioral disturbance (see box on Lead Poisoning). In liver disease, there may be increased urinary excretion of coproporphyrin, predominantly isomer I. In the Dubin-Johnson syndrome, the ratio of coproporphyrin isomer I to isomer III is markedly increased in the urine (>80%), possibly as a result of deficiency of hepatic uroporphyrinogen III cosynthase and increased activity of PBGD. In Rotor syndrome, total urinary excretion of coproporphyrin is markedly increased and consists predominantly of coproporphyrin isomer I. In the unconjugated hyperbilirubinemia of Gilbert syndrome, depressed activity of protoporphyrinogen oxidase and increased activity of ALAS has been found in peripheral leukocytes.[226]

Environmental Intolerances

It has been hypothesized that several otherwise-unexplained chemical-associated illnesses, such as multiple chemical sensitivity syndrome, may represent mild chronic cases of porphyria or other acquired abnormalities in heme synthesis. However, evidence for this concept is lacking.[225,227]

Lead Poisoning

It has been known for some time that patients suffering from lead poisoning have an accumulation of protoporphyrin in erythrocytes and increased urinary excretion of ALA and coproporphyrin.[224] There are sex-related differences in the porphyrin synthetic response to lead, with females showing a more profound coproporphyrinuria than men.[225] The elevated protoporphyrin chelated by zinc is retained in the erythrocyte, which may explain the absence of photosensitivity. This accumulation of porphyrins and precursors is caused by the inhibition by lead of the heme biosynthetic enzymes: 5-aminolevulinate (ALA) dehydratase, coproporphyrinogen oxidase, and ferrochelatase. An increase in the activity of the rate-controlling enzyme ALA synthase (ALAS) results.

Many of the clinical manifestations of lead poisoning may be the result of altered heme biosynthesis.[72] A mild to moderate anemia that can be hypochromic and microcytic occurs in a minority of patients, whereas basophilic stippling is prominent due to inhibition of pyrimidine 5′-nucleotidase in the maturing reticulocyte. Ring sideroblasts have not been reported. The abdominal pain, constipation, and peripheral neuropathy that occur in lead poisoning are also seen in acute attacks of hepatic porphyria. Neuropathy, seen in lead poisoning, may also be the result of disorders of heme biosynthesis, as in the porphyrias.[224] Alterations in porphyrin metabolism have provided a useful means of detecting and assessing the severity of lead exposure and poisoning. The diminution in activity of erythrocyte ALA dehydratase and elevated erythrocyte protoporphyrin levels are the most sensitive measures.

CHAPTER 37

MEGALOBLASTIC ANEMIAS

Aśok C. Antony

The term *megaloblastic anemia* is used to describe a group of disorders characterized by a distinct morphologic pattern in hematopoietic cells. A common feature is a defect in deoxyribonucleic acid (DNA) synthesis, with lesser alterations in ribonucleic acid (RNA) and protein synthesis, leading to a state of unbalanced cell growth and impaired cell division. Most megaloblastic cells are not resting but vainly engaged in attempting to double their DNA, with frequent arrest in the S phase and lesser degrees of arrest in other phases of the cell cycle. An increased percentage of these cells have DNA values between 2 N (N is the amount of DNA in the haploid genome) and 4 N because of delayed cell division. This increased DNA content in megaloblastic cells is morphologically expressed as larger-than-normal "immature" nuclei with finely particulate chromatin, whereas the relatively unimpaired RNA and protein synthesis results in large cells with greater "mature" cytoplasm and cell volume. The net result of megaloblastosis is a cell whose nuclear maturation is arrested (immature) while its cytoplasmic maturation proceeds normally independently of the nuclear events. The microscopic appearance of this nuclear-cytoplasmic asynchrony (or dissociation) is morphologically described as megaloblastic. Each cell lineage has a limited but unique repertoire of expression of defective DNA synthesis. This is significantly influenced by the normal patterns of maturation of the affected cell line. Additional variables that affect RNA and protein synthesis can lead to the attenuation or modification of megaloblastic expression (see Masked Megaloblastosis).

Megaloblastic hematopoiesis commonly manifests as anemia, but this feature is only a manifestation of a more global defect in DNA synthesis that affects all proliferating cells. The peripheral blood picture is characteristic and reflective of megaloblastic hematopoiesis within the bone marrow. The diagnosis is therefore usually straightforward, but because any condition that specifically perturbs DNA synthesis may lead to megaloblastosis, determination of the precise cause is necessary before institution of therapy. Inappropriate therapy can lead to disastrous consequences for the patient. The biochemical basis for megaloblastosis needs to be understood within the context of evaluation of potential and real variables affecting DNA, RNA, and protein synthesis in a given patient. The most common causes of megaloblastosis are true cellular deficiencies of vitamin B_{12} (cobalamin) or folate, vitamins that are essential for DNA synthesis.

Because of the imperative for conservation of cobalamin within the body, there is a finely tuned mechanism in place to ensure a sequential handover of this precious cargo from one protein to another—from the point of its entry into the mouth through the gut, across the enterocyte, into the circulation with specialized uptake into cells, passage through lysosomes into cytoplasm, and even into mitochondria. Throughout this odyssey cobalamin is accompanied by several chaperones that sequentially bind, sequester, and thereby ensure that cobalamin does not participate in side reactions. This ensures its fitness for service for critical enzymes.

Despite the greater abundance of folate in the diet relative to cobalamin, there are also specialized means to ensure that the natural folates in food are first chopped and diced before being ushered across the enterocyte through specialized pathways. After passage from the portal blood into the general circulation, folate is extracted by cell surface folate receptors, undergoes endocytosis, and is then shunted together with a proton across another channel into the cytoplasm. It is then received by an overabundance of high-affinity multifunctional enzymes that channel the folate across set pathways to support critical synthesis of thymidine for DNA.

Indeed, the care with which cobalamin and folate is handled is analogous to the swarm of Secret Service agents escorting a president as he walks by a crowd of well-wishers, their sole aim being to prevent him from getting too close to the public—to shake hands, or hug and kiss a baby, and the like, which could also expose him to potential harm by an ill-wisher—and detract him from doing his primary job as chief executive.

The pathophysiology of cellular cobalamin and folate deficiency is most readily discerned by the clinician who approaches megaloblastosis with a clear understanding of the physiology of these vitamins. A detailed discussion of cobalamin and folate therefore follows.

COBALAMIN

The term *cobalamin* refers to a family of compounds with the structure shown in Fig. 37-1. Details of the chemistry, nomenclature, and in vivo substitutions of cobalamin are shown in Figs. 37-1 to 37-3, and excellent reviews are available on the colorful history, chemistry, and biology of cobalamin.[1-4]

Nutrition

Cobalamin is produced in nature only by microorganisms, and humans receive cobalamin solely from the diet.[5] Cobalamin is synthesized and used by some microorganisms (e.g., bacteria, fungi). Some strains produce cobalamin in excess of their requirements, making them excellent and cheap commercial sources for cobalamin used in therapy. Herbivores obtain their dietary quota of cobalamin from plants contaminated with cobalamin-producing soil bacteria (rhizobia) that grow in roots and nodules of legumes. Because rhizobia-related organisms are also found in the large intestine of animals (and humans), volitional or inadvertent coprophagy can lead to intake of cobalamin by herbivores; however, cobalamin from manure that contaminates plants is not likely to be a significant source for humans.[5] Nevertheless, colonic cobalamin-producing bacteria—like *Klebsiella pneumoniae* that are related to rhizobia—can be found in the small intestine of some individuals from which cobalamin can be absorbed. Because microscopic insects found in vegetables (cabbage, lettuce, spinach) can be unwittingly consumed, in theory, "organically grown" leafy vegetables may have higher cobalamin than those exposed to chemical fertilizers, but this awaits confirmation.[6] For all practical purposes, there is *no* unfortified plant food, including fermented soy products, tempeh/*tempe,* seaweed—(which are actually multicellular algae, such as nori [red algae], chlorella [green algae], spirulina [blue-green algae]—or other organic produce that can consistently provide a sufficient amount of active cobalamin to support daily requirements.

Animal protein is the major dietary cobalamin source for nonvegetarians. Meats from parenchymal organs are richest in cobalamin (over 10 mcg/100 g wet weight); fish and muscle meats, milk

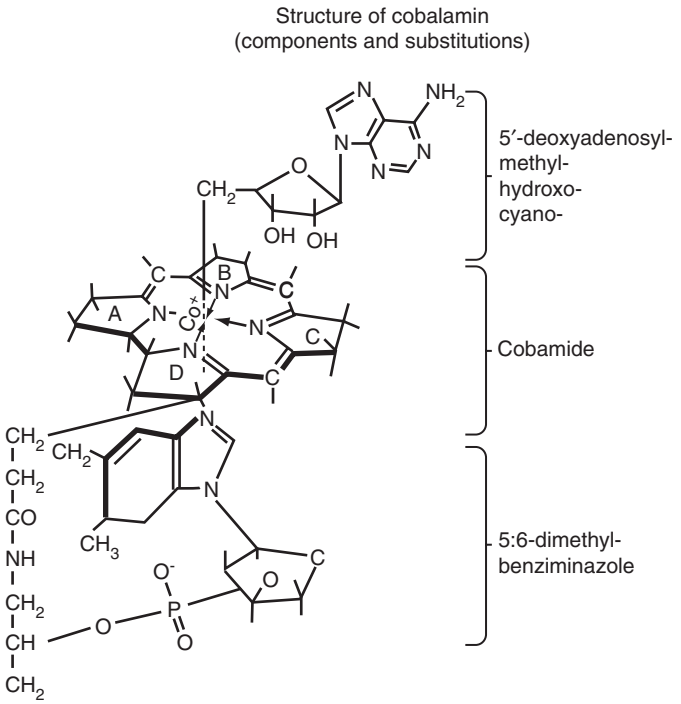

Figure 37-1 COBALAMIN (VITAMIN B_{12}) CHEMISTRY AND NOMENCLATURE. The central cobalt atom of cobalamin forms the focal point of this large complex organometallic molecule (approximately 1300 to 1500 Da). There are up to six ligands that can bind to this cobalt; of these, four involve nitrogen atoms of the planar corrin ring that surround the cobalt atom. The lower α-axial ligand, extending perpendicular below the corrin ring, links to nitrogen of a 5,6-dimethylbenzimidazole phosphoribosyl moiety that is also attached back to the corrin ring through one of its propionamide side chains (this is analogous to the hand guard on the handle on a sabre that covers the knuckles of the hand). The upper or β-axial ligand varies and can exist in the fully oxidized Co^{+++} state, which is referred to as cob(III)alamin; in the Co^{++} state, called cob(II)alamin (which can be used for the synthesis of methylcobalamin or adenosylcobalamin); or the fully reduced Co^{+} state (cob[I]alamin). These upper axial ligands include cyano- (cyanocobalamin), hydroxyl- (hydroxocobalamin), methyl- (methylcobalamin), or 5′-deoxyadenosyl- (adenosylcobalamin) and confer a distinct identity to cobalamin for participation in one-carbon metabolism. All these forms with substituted upper axial ligands are cob(III)alamins, which adopt a configuration in which the 5,6-dimethylbenzimidazole nitrogen base is coordinated to the cobalt in the lower axial position. This is referred to as the "base-on" position. However, when cobalamin is bound to the enzymes methionine synthase and methylmalonyl-CoA mutase, another conformational change results in the replacement of the 5,6-dimethylbenzimidazole by a histidine donated by the enzyme; this is the "His-on" position. Thus shifts from "base-on/His-off" conformation to an alternative "base-off/His-on" conformation have an important bearing on the catalytic activity of these enzymes. Conversion of cyanocobalamin to its active cofactor forms requires a decyanation step. *(From Chanarin I:* The megaloblastic anemias, *Oxford, UK, 1979, Blackwell Scientific Publications.)*

products, and egg yolk have 1 to 10 mcg/100 g of wet weight. An average nonvegetarian Western diet contains 5 to 7 mcg/day of cobalamin, which adequately sustains normal cobalamin equilibrium. A vegetarian diet supplies between 0.25 and 0.5 mcg/day of cobalamin, so most vegetarians *do not* receive adequate dietary cobalamin and are at risk for cobalamin deficiency.[7] The recommended daily allowance is 2.4 mcg for men and nonpregnant women, 2.6 mcg for pregnant women, 2.8 mcg for lactating women, and 1.5 to 2 mcg for children 9 to 18 years old.[6]

Food cobalamin is stable to high-temperature cooking but is readily converted to inactive cobalamin analogues by ascorbic acid. Cobalamin is exceptionally well stored in tissues in its coenzyme forms. Of the total-body content of 2 to 5 mg in adults, about 1 mg is in the liver. There is an obligatory loss of 0.1% per day (1.3 mcg) regardless of total-body cobalamin content. It takes about 3 to 4 years to deplete cobalamin stores when dietary cobalamin is abruptly malabsorbed, but it may take longer to develop nutritional cobalamin deficiency, because of an efficient enterohepatic circulation, which accounts for turnover of 5 to 10 mcg/day of cobalamin.[8]

Absorption

Cobalamin in food is usually in coenzyme form (5′-deoxyadenosylcobalamin [adenosylcobalamin] and methylcobalamin), nonspecifically bound to proteins (see Fig. 37-2). In the stomach, peptic digestion at low pH is a prerequisite for cobalamin release from food protein.[8] Once released by proteolysis, cobalamin preferentially binds a high-affinity, 150-kDa, cobalamin-binding protein called *R protein* (a haptocorrin) from gastric juice and saliva that has higher affinity for cobalamin than gastric intrinsic factor (IF). The cobalamin–R protein (holo-R protein) complex, along with excess unbound (apo)-R protein and IF, pass through into the second part of the duodenum, where pancreatic proteases degrade holo-R and apo-R proteins (but not IF). This results in the transfer of cobalamin to IF, a 45-kDa glycoprotein with high-affinity binding ($K_a = 1.5 \times 10^{10}\ M^{-1}$), 1:1 molar stoichiometry, stability, and resistance to proteolysis over a pH range of 3 to 9.[8] Failure to degrade holo-R proteins by pancreatic protease precludes the involvement of IF in cobalamin absorption because the downstream ileal IF-cobalamin receptors only interact with IF-bound cobalamin.[8] Although R proteins bind cobalamin and most cobalamin analogues with comparably high affinity, IF only binds cobalamin.

IF is produced in parietal (oxyntic) cells in the fundus and cardia of the stomach[8] and is released by membrane-associated vesicular transport.[8] IF has two binding sites: one for cobalamin and another for the ileal IF-cobalamin receptor. IF is produced in far greater excess than is actually required for absorption,[8] and the IF in only 2 to 4 mL of normal gastric juice can reverse cobalamin deficiency in adults who lack IF. In the absence of IF, less than 2% of ingested cobalamin is absorbed, whereas in its presence, approximately 70% is absorbed.

IF is secreted in response to food in the stomach in a manner analogous to secretion of acid (i.e., by vagal and hormonal stimulation). IF binds biliary cobalamin and newly ingested cobalamin following its transfer from R protein.[8,9] Because biliary cobalamin analogues are not transferred from R protein to IF, this is an efficient method for fecal excretion of cobalamin analogues while allowing for reabsorption of biliary cobalamin. The stable IF-cobalamin complex passes through the jejunum to the ileum, where specific membrane-associated IF-cobalamin receptors for IF-cobalamin are located on microvilli of ileal mucosal cells.[8]

The functional IF-cobalamin receptors are composed of a complex of two proteins collectively known as cubam—composed of *cub*ilin[10] and *am*nionless[11]—that is essential to complete transport of the IF-cobalamin complex from the intestinal lumen into the enterocyte. Cubilin is the large 400-kDa extracellular portion of the cubam complex; it is anchored to the membrane by amnionless, which is nearly one-tenth its size; both are however dependent on one another for proper localization as cubam in the membrane. Dysfunction of cubam is the basis for Imerslund-Gräsbeck syndrome. These IF-cobalamin receptors (cubam) require Ca^{2+} for binding at pH above 5.4; they do not bind free IF, cobalamin, or R protein–bound cobalamin; so these receptors are highly specific and have a high affinity for IF-cobalamin ($K_a = 1 \times 10^{9}\ M^{-1}$). The human ileum contains enough cubam receptors to bind up to 1 mg of IF-bound cobalamin; this is the rate-limiting factor in cobalamin absorption.[8]

After the cobalamin-IF complex is internalized by cubam receptor for subsequent processing, cubam is recycled to the cell surface, whereas cobalamin enters the cytoplasm. Subsequent physiologic events are unclear. Although multidrug resistance–associated protein 1 (MRP1) may act as the molecular gate for the cellular export of cobalamin across the basolateral membrane of intestinal epithelium

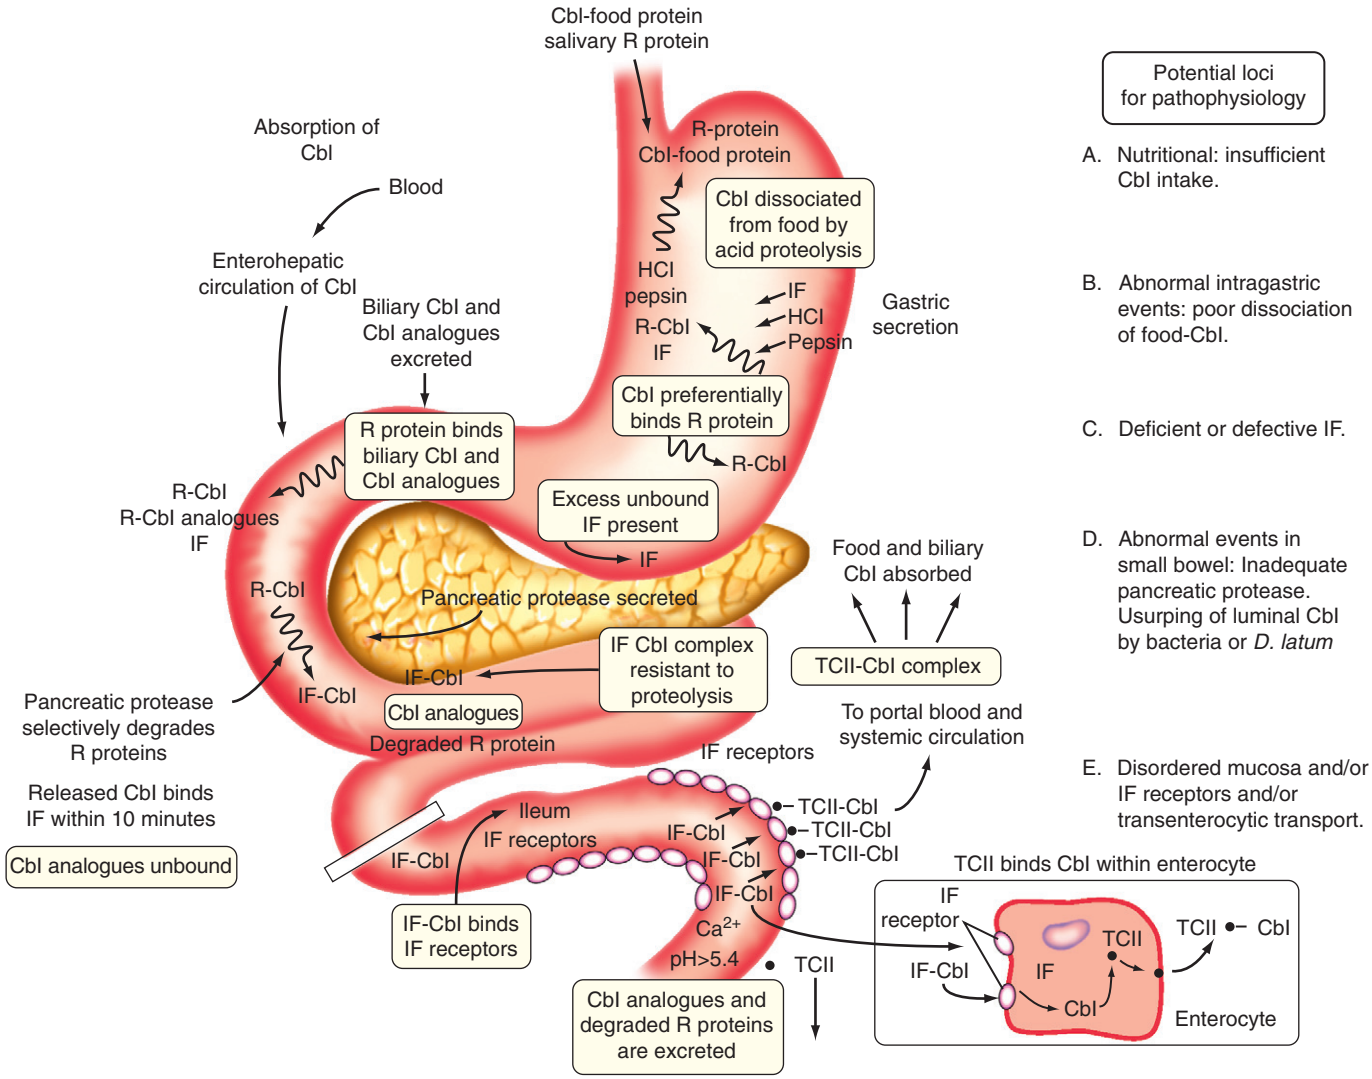

Figure 37-2 COMPONENTS AND MECHANISM OF COBALAMIN ABSORPTION. *Cbl,* Cobalamin; *D. latum, Diphyllobothrium latum; HCl,* hydrochloric acid; *IF,* intrinsic factor; *R-Cbl,* R-protein bound cobalamin; *TCII,* transcobalamin II.

and in other cells,[12] studies on mutated MRP1 fail to identify defects in cobalamin absorption[13]; so a physiologic role for MRP1 is still unclear. The next step involves interaction with transcobalamin II (TCII), which is secreted unidirectionally across the basolateral surface, and cobalamin apparently binds TCII within or at the basal surface of the ileal enterocyte.[8] TCII, which is abundant in the microvascular endothelium, is also available to bind cobalamin. After 3 to 5 hours, cobalamin appears in portal blood largely (over 90%) bound to TCII and reaches peak levels in about 8 hours.[8]

Cobalamin in large doses can also passively diffuse through buccal, gastric, and jejunal mucosa so that less than 1% of a large dose of oral cobalamin appears in the circulation within minutes. This property is used to advantage in individuals with cobalamin malabsorption in lieu of parenteral replacement (discussed later).[8]

Transport

More than 90% of recently absorbed or injected cobalamin is bound to TCII, which is the specific transport protein for delivery of cobalamin to tissues. TCII, a 38-kDa polypeptide synthesized in many tissues, binds cobalamin with 1:1 molar stoichiometry and high affinity ($K_a = 1 \times 10^{11}\ M^{-1}$).[9] The TCII-cobalamin complex is rapidly cleared from the circulation in less than an hour. TCII-bound cobalamin binds to specific cell surface TCII-cobalamin receptors present on several cells.[14,15] High-affinity TCII-cobalamin binding to TCII receptors is specific only for holo- and apo-TCII ($K_a = \sim 5 \times 10^{10}\ M^{-1}$). Because some cobalamin analogues can bind TCII with high affinity, these also have the same potential for cellular uptake as cobalamin.[8]

Circulating cobalamin, which is predominantly in the form of methylcobalamin, is not found free in plasma. Binding to TCII accounts for only 10% to 30% of the total serum cobalamin, with the majority (approximately 75%) of remaining cobalamin being bound to another protein, transcobalamin I (TCI). TCI (another haptocorrin) binds biologically active cobalamins as well as biologically inactive cobalamin derivatives. Because TCI is not a transport protein, it is best viewed as a plasma-storage form of cobalamin; indeed, cobalamin-bound TCI has a slow clearance rate (half-life of 9 to 12 days).[9] A third transport protein, transcobalamin III (TCIII), is closely related to TCI but has a half-life in minutes because it is an asialoglycoprotein. TCIII binds a wide spectrum of cobalamin analogues with high affinity and delivers them via hepatic asialoglycoprotein receptors to hepatic cells, and thence into bile for fecal excretion. Between 0.5 and 9 mcg of cobalamin taken up by hepatic TCII receptors is secreted into bile, of which approximately 75% is reabsorbed, analogous to food cobalamin,[8] reflecting an efficient enterohepatic circulation of cobalamin.

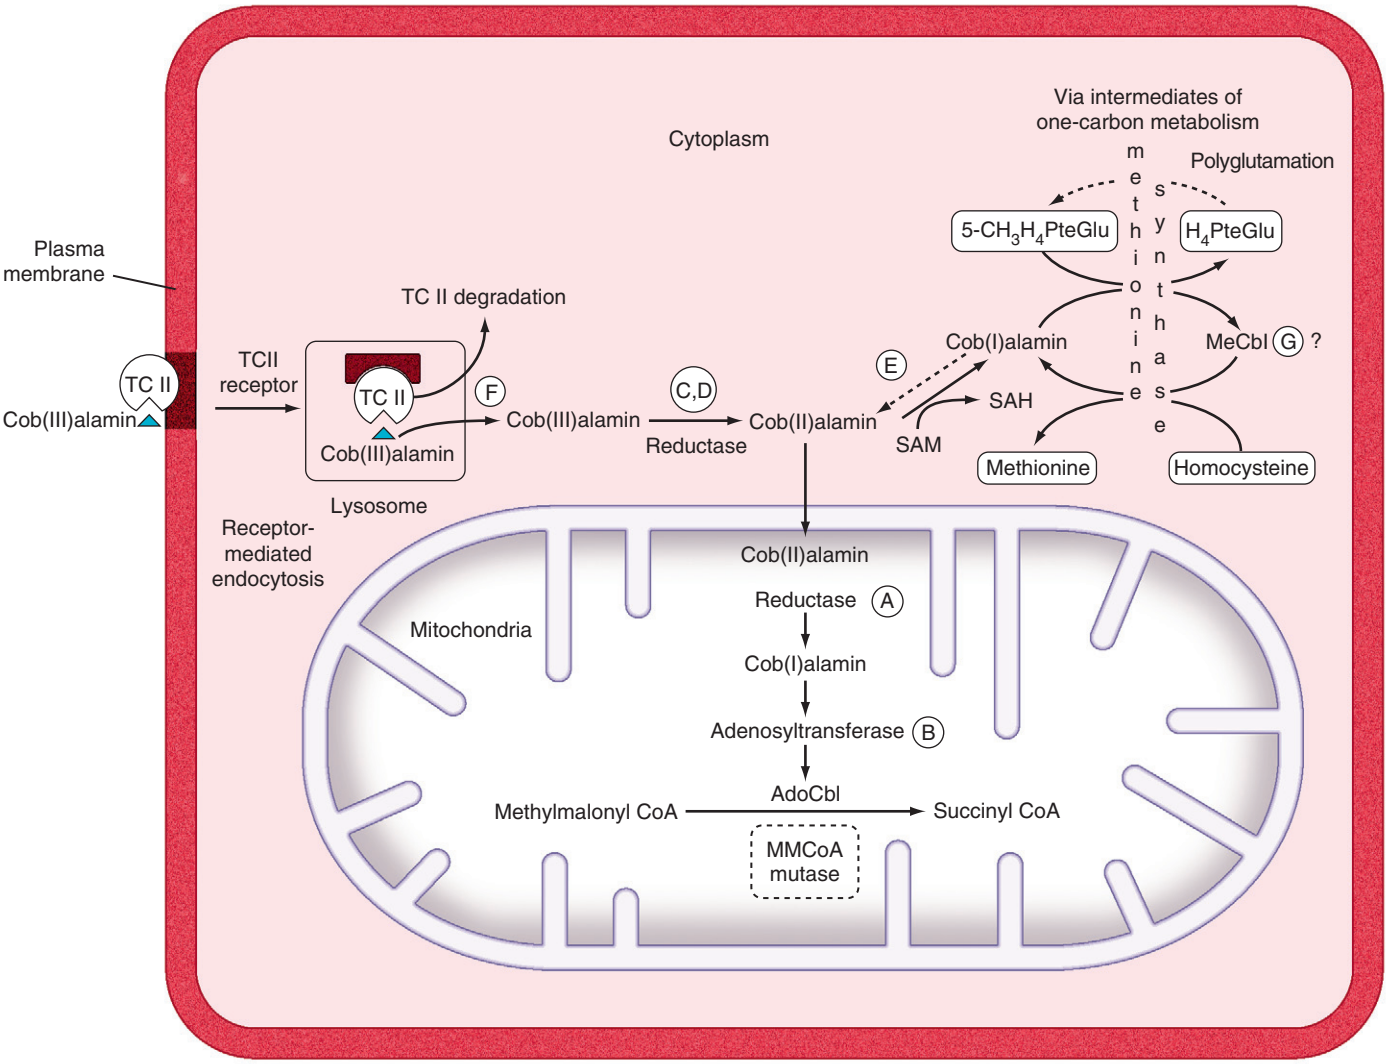

Figure 37-3 CELLULAR UPTAKE AND INTRACELLULAR REACTIONS INVOLVING COBALAMIN. A large family of natural and synthetic cobalamins can be generated when the cyanide (CN) moiety (upper axial ligand in cyanocobalamin) is replaced. On exposure to light, CN is gradually lost from cyanocobalamin, with the production of hydroxocobalamin. In vivo substitutions include the replacement of hydroxocobalamin or cyanocobalamin by a 5′-deoxyadenosyl group attached by a covalent bond, giving rise to adenosylcobalamin (AdoCbl). Methylcobalamin (MeCbl) is the main form in plasma. In vivo, 5-methyl-tetrahydrofolate readily donates its methyl group to cob(I)alamin in a reaction involving methionine synthase to form methylcobalamin. The approximate loci for defects in cobalamin mutants, cblA to cblG, are shown. See text for details. *MMCoA mutase,* Methylmalonyl-CoA mutase; *SAH, S*-adenosylhomocysteine; *SAM, S*-adenosylmethionine.

Cellular Processing

Once bound to TCII receptors, the TCII-cobalamin complex is internalized by conventional receptor-mediated endocytosis (see Fig. 37-3).[8] At the low pH extant in lysosomes, TCII dissociates from cobalamin and is degraded, whereas cobalamin is transported by the lysosomal transporter, LMBRD1 protein,[16] into the cytosol as a mixture of cob(III)alamin and cob(II)alamin. LMBRD1 is missing in cblF mutation (see Fig. 37-3). Cob(III)alamin, the most "oxidized" form of cobalamin, must be converted to cob(II)alamin and cob(I)alamin by two sequential reductase steps (see Fig. 37-3). Once in the cytoplasm, cobalamin is bound to MMACHC, an enzyme that catalyses removal of the cyano or methyl or adenosyl groups that are bound to cobalt in the cobalamin molecule.[17] From here, cobalamin is moved to target enzymes in the mitochondria or the cytoplasm.

More than 95% of intracellular cobalamin is bound to two intracellular enzymes, methylmalonyl-CoA mutase and methionine synthase.[8] When cobalamin interacts with its target enzymes, it exists in a "base-off/His-on" conformation, which reflects a very close relationship with these enzymes (see legend for Fig. 37-1).

In mitochondria, cob(I)alamin is converted to its coenzyme form, adenosylcobalamin, which acts as a coenzyme with methylmalonyl-CoA mutase to mediate the intramolecular exchange of a hydrogen atom attached to one carbon atom with a group attached to an adjacent carbon atom; in this way, methylmalonyl-CoA is converted to succinyl-CoA. (Methylmalonyl-CoA is normally generated during the catabolism of branched-chain amino acids, odd-chain fatty acids, and cholesterol. When formed, succinyl-CoA can then enter the Krebs tricarboxylic acid cycle.)

In the cytoplasm, cobalamin, as methylcobalamin, functions as a coenzyme for methionine synthase, a critical enzyme for which both folates and cobalamin are required for normal one-carbon metabolism (see Fig. 37-3). Methionine synthase is a modular protein with four distinct and separate regions for binding homocysteine, 5-methyl-tetrahydrofolate (5-methyl-THF; 5-methyl-H_4PteGlu), the cobalamin prosthetic group, and *S*-adenosylmethionine (SAM).[9] The reaction proceeds by methyl transfer from 5-methyl-tetrahydrofolate to methionine synthase–bound cob(I)alamin to form methylcobalamin, followed by transfer of this methyl group to homocysteine to form methionine and regeneration of cob(I)alamin. In this process,

5-methyl-tetrahydrofolate is converted to tetrahydrofolate. During this reaction, spontaneous oxidation of cob(I)alamin (which has no axial ligand) to the catalytically inactive cob(II)alamin form can occur about once in every 1000 to 2000 catalytic cycles[18]; this requires reduction back to cob(I)alamin before it can accept a methyl group. There is a specific redox regulator known as methionine synthase reductase that restores enzyme activity in the presence of SAM and NADPH[19]; this enzyme is mutated in patients with cblE mutations.

The physiologic importance of the key cofactor roles of the two forms of cobalamin (i.e., adenosylcobalamin and methylcobalamin) in methylmalonyl-CoA mutase and methionine synthase, respectively, is that the products and by-products of these enzymatic reactions are critical for DNA, RNA, and protein biosynthesis.

FOLATES

Nutrition

Folates (the anionic forms of folic acid, also called vitamin B_9), are synthesized by microorganisms and plants, including leafy vegetables (spinach, lettuce, broccoli), beans, fruits (bananas, melons, lemons), yeast, and mushrooms, and are also found in animal meats[8]; see Fig. 37-4 for chemistry and nomenclature.

Among natural folates, which are predominantly in polyglutamylated form, only one-half are bioavailable; by contrast, 85% of folic acid that is added to food or ingested as a supplement is bioavailable. Several factors can influence the bioavailability of folates. These include the following: (1) The stability of the food folate affects its bioavailability. Natural reduced folates are labile and susceptible to oxidative cleavage by nitrates or light exposure, but folic acid is much more stable. Prolonged boiling or cooking for over 30 minutes reduces natural folates by 50% to 80%, whereas ascorbate increases bioavailability, and refrigeration of leafy foods exposed to artificial fluorescent light in supermarkets can double the folate content.[21] (2) Pureed foods allow easier access to the glutamate carboxypeptidase II (also known as folate-polyglutamate hydrolase), which converts folate polyglutamates to simpler folate monoglutamates before absorption[22]; any perturbation of this enzyme by organic acids (orange juice), sulfasalazine, or ethanol can preclude absorption; conversely, folate-binding proteins in human or cow's milk can increase folate absorption for infants and women.[23] (3) Interference with folate absorption across the proximal jejunum from intestinal diseases will affect the bioavailability of food folate. (4) Drugs that interfere with the proton-coupled folate transporter (PCFT) can also compromise folate absorption.

The recommended daily allowance of folate is as follows: adult men and nonpregnant women, 400 mcg; pregnant women, 600 mcg; lactating women, 500 mcg; children 9 to 18 years, between 300 and 400 mcg.[6] A balanced Western diet contains adequate amounts of folate, but the net dietary intake of folate in many developing countries is often insufficient to sustain folate balance.[8,9,24,25]

Absorption

After dietary folate polyglutamates are converted to folate monoglutamates at the enterocyte brush border, they are transported through the duodenal and jejunal brush border by physiologically relevant, high-affinity membrane-associated, luminal surface–facing proton-coupled folate transporters (PCFT), which are most efficient in an acidic milieu. At pH 5.5, there is equivalent affinity for transport of physiologic reduced folates and folic acid, but at pH 6.5, reduced 5-methyl-tetrahydrofolate is transported more efficiently.[26] PCFT is a folate-hydrogen symporter, so with each folate molecule transported, there is a net translocation of positive charge. Loss-of-function mutations in PCFT in the enterocyte and choroid plexus result in (congenital) hereditary folate malabsorption,[27,28] a condition associated with an inability to transport folate across the intestine and the choroid plexus. The expression of PCFT is increased in folate-deficient mice, suggesting a physiologic regulatory mechanism. Proton pump inhibitors can reduce expression, and blocking the function of PCFT by sulfasalazine and pyrimethamine can lead to acquired folate malabsorption.[28,29] Within the enterocyte, folates are reduced to tetrahydrofolate and methylated before release into plasma as 5-methyl-tetrahydrofolate. Most of the folic acid taken up by the PCFT in the proximal small intestine is also converted within the enterocyte to 5-methyl-tetrahydrofolate.

The flux of folate from the basolateral membrane of the enterocyte to the portal blood is mediated through multidrug resistance–associated protein 3 (MRP3).[28] MRP proteins have low affinity but high capacity and are best visualized as cellular "sump pumps" that eject excess folates (and antifolates) out of cells. Together with MRP2, which mediates folate transport into the bile,[30] these MRPs maintain an efficient enterohepatic circulation, which helps the body retain folate.[28]

Some bacterially produced folate can be absorbed across the large intestine,[31] but this accounts for no more than about 5% of the average folate requirement and likely supports the nutrition of colonocytes.

Passive diffusion of folic acid (pteroylmonoglutamate [PteGlu]) is probably the primary mechanism of intestinal mucosal folate

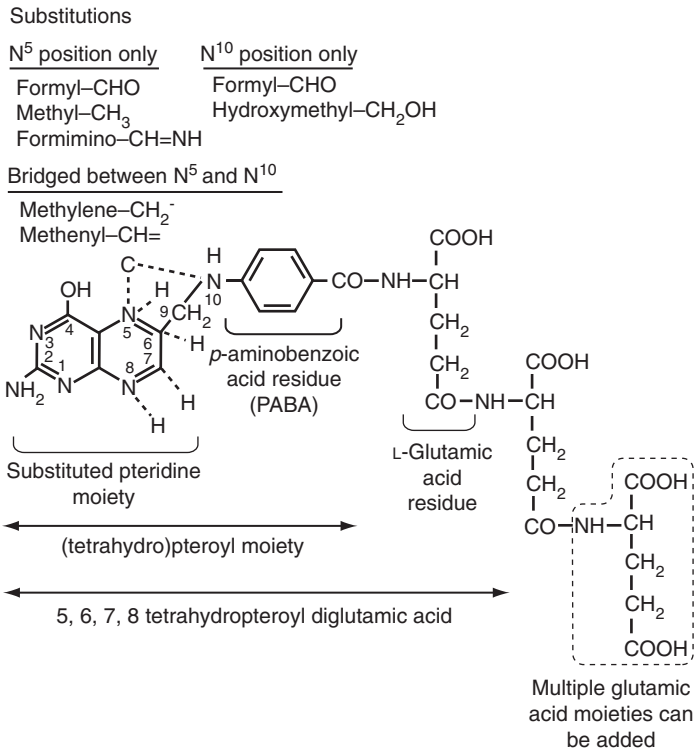

Figure 37-4 FOLATE CHEMISTRY AND NOMENCLATURE. Folic acid (pteroylmonoglutamate [PteGlu]) is the commercially available parent compound for more than 100 compounds collectively referred to as *folates*. PteGlu consists of three basic components: a pteridine derivative, a *p*-aminobenzoic acid residue, and an L-glutamic acid residue. Before PteGlu can play a role as a coenzyme, it must first be reduced at positions 7 and 8 to dihydrofolic acid (H_2PteGlu) and then to 5,6,7,8-tetrahydrofolic acid (THF; H_4PteGlu), and one to six additional glutamic acid residues must then be added by means of γ-peptide bonds to the l-glutamate moiety (for which the subscripted *n* in $PteGlu_n$ denotes polyglutamation). Folate coenzymes donate or accept one-carbon units in numerous reactions in amino acid and nucleotide metabolism. The various substitutions in $H_4PteGlu_n$ occur at positions 5 or 10, or both; position 5 can be substituted by methyl (CH_3), formyl (CHO), or formimino (CHNH), and position 10 can be substituted by formyl or hydroxymethyl (CH_2OH). Positions 5 and 10 can be bridged by methylene (–CH_2–) or methenyl (–CH=). For an engaging account of the history of folic acid, see reference 20.

absorption at high pharmacologic concentrations.[8] The small intestine has a large capacity to absorb folate, with peak folate levels in plasma achieved 1 to 2 hours after oral administration.

Plasma Transport and Enterohepatic Circulation

The normal serum folate level is maintained by dietary folate and a substantial enterohepatic circulation that amounts to about 90 mcg/day of folate.[8] Biliary drainage results in a dramatic fall in serum folate (to about 30% of basal levels in 6 hours), whereas abrupt interruption of dietary folate leads to a fall in serum folate levels in about 3 weeks. In the plasma, one-third of the folate is free, two-thirds is nonspecifically bound to serum proteins, and a small fraction binds high-affinity, hydrophilic 40-kDa folate-binding proteins, which are structurally related to hydrophobic (native) folate receptors.[32] However, in contrast to cobalamin uptake, there is no specific *serum* transport protein that enhances cellular folate uptake.

Cellular Folate Uptake

Folate Receptors

Plasma 5-methyl-tetrahydrofolate and folic acid are rapidly transported into proliferating cells by specialized, high-affinity, glycosylphosphatidylinositol-anchored (membrane) folate receptor-α, which takes up these folates at physiologic concentrations found in serum.[28,32] The plasma membrane containing the folate–folate receptor complex then invaginates and forms an endosomal vesicle that moves into the cytoplasm along microtubules. The perinuclear endosomal compartment then gets acidified to pH 6, which dissociates folate from folate receptors. The released folate then passes across the acidified endosome into the cytoplasm by a transendosomal pH gradient, which is mediated by the PCFT or related moiety[27,28] (Fig. 37-5).

Folate receptor-α is critical to mediating the cellular uptake of folates in proliferating malignant and normal cells and in transport

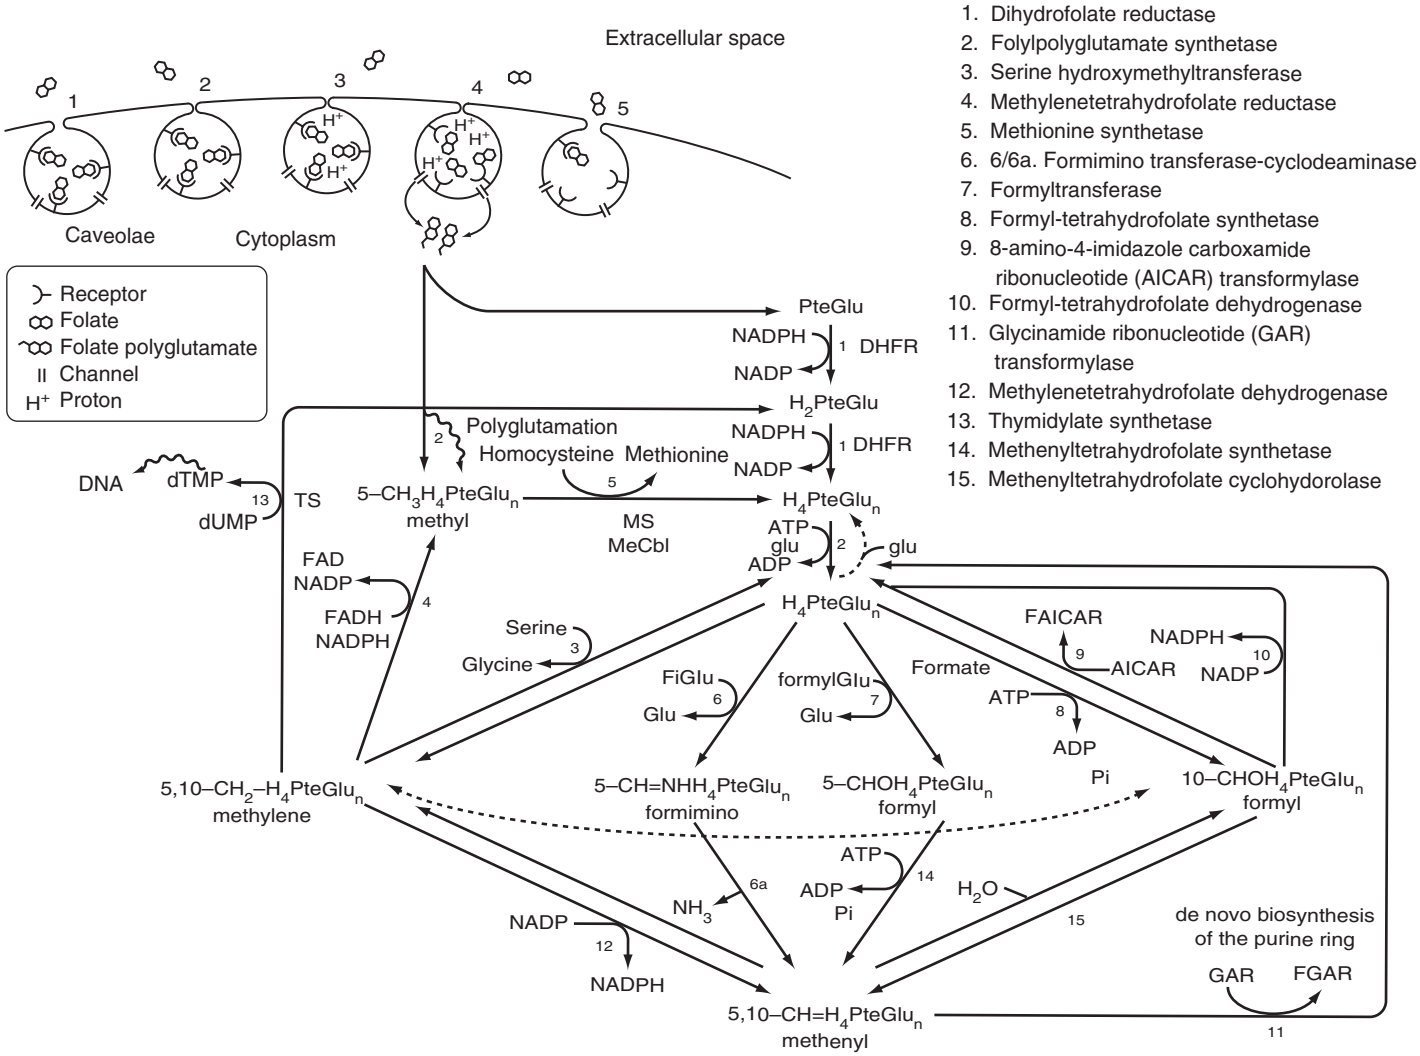

Figure 37-5 FOLATE RECEPTOR-COUPLED FOLATE UPTAKE AND INTRACELLULAR ONE-CARBON METABOLISM INVOLVING FOLATES. See text for details. The channel within the caveolae/endocytotic vesicle is related to the proton-coupled folate transporter (PCFT). The contribution of the reduced folate carrier–mediated transport and passive diffusion of folate into cells is not shown. *ADP,* Adenosine diphosphate; *ATP,* adenosine triphosphate; *DHFR,* dihydrofolate reductase; *DNA,* deoxyribonucleic acid; *dTMP,* deoxythymidine monophosphate; *dUMP,* deoxyuridine monophosphate; *FAD,* flavin adenine dinucleotide; *FADH,* the reduced form of flavin adenine dinucleotide; *FiGlu,* formimino glutamic acid; *Glu,* glutamic acid; *NADP,* nicotinamide adenine dinucleotide phosphate; *NADPH,* the reduced form of nicotinamide adenine dinucleotide phosphate. *(Modified from Shane B, Stokstad EL: Vitamin B_{12}-folate interrelationships.* Annu Rev Nutr *5:115, 1985; and Rothberg KG, Ying Y, Kolhouse JF, et al: The glycophospholipid-linked FR internalizes folate without entering the clathrin-coated pit endocytic pathway.* J Cell Biol *110:637, 1990.)*

of folate across the placenta to the fetus,[33] into the brain,[27,32,34] and in renal conservation of folates. Folate receptor-α is expressed in several types of cancer cells, whereas folate receptor-β is expressed most in monocytes and macrophages[35]; hence these folate receptors are under intense scrutiny for potential clinical use in detecting (and treating) occult malignancy and inflammation.[35]

The physiologic role of the reduced-folate carrier is less clear; it is a "low-affinity" but "high-capacity" system that can also mediate the uptake of 5-methyl-tetrahydrofolate and pharmacologic folates (like methotrexate and folinic acid well, but folic acid poorly) into a variety of cells at physiologic pH.[28]

Folate Receptor Regulation and Cellular Folate Homeostasis

Cell surface folate receptor-α is upregulated in response to low extracellular and intracellular folate concentrations through transcriptional, translational, and posttranslational mechanisms.[32,36-38] Poised in this location facing the external milieu of cells, upregulated folate receptor-α can bind all available folate and thereby restore cellular folate homeostasis.

The answer to the more fundamental question—how do cells sense the existence of folate deficiency in the first place so that folate homeostasis can be subsequently restored by upregulating folate receptors?—has finally been discovered.[39] It so happens that the accumulation of intracellular homocysteine during cellular folate deficiency leads to the covalent binding (by homocysteine) of a protein known as heterogeneous nuclear ribonucleoprotein-E1 (hnRNP-E1), which is already known to mediate the translational upregulation of folate receptor-α.[37,40] Homocysteinylation of hnRNP-E1 at specific cysteine–cysteine disulfide bonds leads to the unmasking of an underlying messenger RNA (mRNA)-binding pocket for which folate receptor-α mRNA has a high affinity. This RNA-protein interaction then triggers the biosynthesis of folate receptors, which soon results in a net increase of cell surface folate receptors that are able to bind more available folate and thereby normalize cellular folate levels. In this context, hnRNP-E1 fulfils criteria as a cellular sensor of physiologic folate deficiency (Fig. 37-6) because this protein is able to sense folate deficiency (by interacting with homocysteine) and respond by increasing RNA-protein interaction that triggers the biosynthesis and upregulation of folate receptors.

The broader significance of this mechanism is that *homocysteinylated hnRNP-E1 actually orchestrates a nutrition-sensitive posttranscriptional RNA operon during folate deficiency*. This means that during folate deficiency, the mRNA-binding pocket within homocysteinylated-hnRNP-E1 is actually highly promiscuous, in that it allows the binding of a variety of very diverse mRNAs (perhaps over 100), all of which have a common password composed of short RNA sequences; these RNA-protein interactions can, in turn, trigger the modulation up or down of a variety of several otherwise entirely unrelated proteins that contribute to the biologic features of reduced cell proliferation, differentiation, and apoptosis, which are a hallmark of folate deficiency.[39]

Folate Receptors and Placental Folate Transport

Because fetal and newborn blood folate is invariably more elevated than maternal blood folate, this suggested the existence of a placental mechanism for preferential maternal-to-fetal folate transport. Placental folate receptors[43,44] are abundant and polarized to the maternal-facing microvillous membrane of the syncytiotrophoblast; they are not present on the basement membrane.[45] Poised in this location, these folate receptors are the first to bind maternal folate at physiologic concentrations and pH; they are critical to transplacental maternal-to-fetal folate transport. This was shown experimentally when irreversible occupancy of the folate-binding site of placental folate receptors led to complete inhibition of transplacental folate transport in an isolated human placental cotyledon perfusion model.[33]

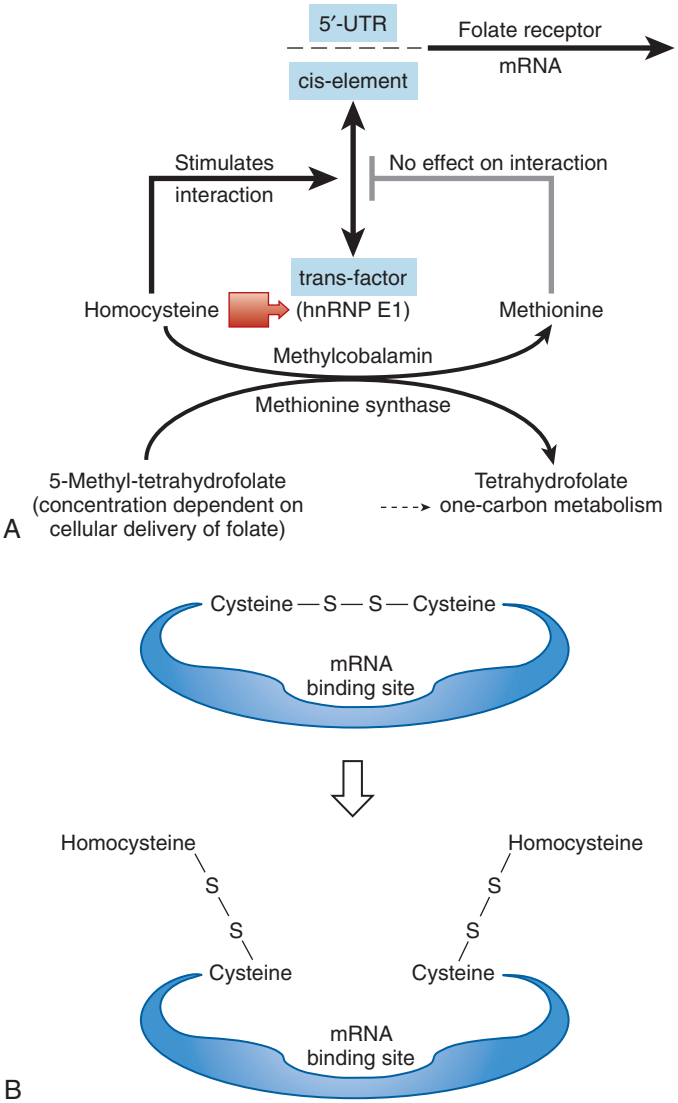

Figure 37-6 MODEL FOR HOW THE CELL SENSES FOLATE DEFICIENCY AND RESPONDS BY UPREGULATING FOLATE RECEPTORS. Note how this model links perturbed folate metabolism, ribonucleic acid (RNA)–protein interaction, and coordinated translational regulation of folate receptor to optimize cellular folate uptake and restore folate homeostasis. The prominent red arrow highlights the critical role of heterogeneous nuclear ribonucleoprotein E1 (hnRNP-E1) as a candidate sensor of cellular folate deficiency. **A,** Reduced folate availability results in inactivation of methionine synthase and intracellular homocysteine buildup, which induces a direct posttranslational homocysteinylation of hnRNP-E1 via targeted homocysteine-S-S-cysteine mixed disulfide bonds; this results in the unmasking of a high-affinity folate receptor messenger RNA (mRNA) cis-element binding site and leads to increased translation of folate receptor-α. The net effect is a homeostatic response that aims to restore intracellular folate concentrations to normal by upregulating cell surface folate receptor. Folate repletion reactivates methionine synthase, which converts homocysteine to methionine. Methionine has no effect on the RNA-protein interaction that leads to reduced folate receptor-α synthesis and its downregulation.[37] (Note: Other metabolic pathways involving homocysteine[41,42] are not included.) **B,** A proposed mechanism for the unmasking of a cryptic mRNA binding site in hnRNP-E1 following the covalent binding of L-homocysteine, through the replacement of one (of many potential) cysteine disulfide bonds by protein-cysteine-S-S-homocysteine mixed disulfide bonds. *5′-UTR,* 5′ Untranslated region. *(From Tang YS, Khan RA, Zhang Y, et al: Incrimination of heterogeneous nuclear ribonucleoprotein E1 (hnRNP-E1) as a candidate sensor of physiological folate deficiency.* J Biol Chem *286:39100, 2011.)*

Physiologic transplacental folate transport, which relies on continued provision of adequate dietary folate intake by the mother, involves capture of maternal folate by placental folate receptors,[43,46] followed by displacement of this pool by incoming dietary folates, which results in an intervillous blood concentration that is three times that of maternal blood. This allows for subsequent transfer of the folate to the fetal circulation along a downhill concentration gradient.[33] This elegant cycle ensures continued unidirectional transplacental folate transport. From a clinical standpoint, a suboptimum intake of folate by the mother that leads to reduction in maternal-to-fetal folate transfer can predispose the embryo/fetus to very serious developmental defects.[47,48]

Because PCFT colocalizes with folate receptor-α, this suggests that following binding and internalization of folate into low-pH endosomes, the folate dissociates from folate receptors and presumably passes via PCFT into the cytoplasm. However, because both PCFT and reduced-folate carriers are uniformly distributed in microvillous membrane, cytoplasm, and the fetal-facing basal plasma membrane,[45] the following are all still unclear: the precise handover of folate following endocytosis into the cytoplasm, the potential role of transcytosis of vesicles containing folate, the transport of folate across the syncytiotrophoblast basement membrane into the fetal vasculature, and the potential role of MRPs in net transplacental folate transport to the fetus.

Indeed, although placental and fetal folate receptors have primary roles in early human development, there is likely to be an important role for PCFT and reduced-folate carriers, because ongoing experimental studies that individually perturb these proteins also induce serious abnormalities in embryonic and fetal development.

Folate Receptors in Embryonic and Fetal Development

Folate receptor-α is among the earliest genes activated in embryonic stem cells[49] when there is the need for increased folate requirements to support DNA synthesis during spectacular bursts of intense cell proliferation, ranging as short as 2 to 3 hours during brief windows within the proliferative zone in the epiblast.[47,50,51] Therefore it can be appreciated why maternal folate deficiency compromises embryonic and fetal development—and perhaps even accounts for an as-yet-uncharacterized number of early miscarriages, as suggested from experimental studies in mice.[48]

Both early-stage neural tube cells and neural crest cells abundantly express folate receptor-α. Experimental perturbation of folate receptor-α can lead to profound abnormalities in neural tube closure and in heart, facial, and eye development.[34,47,52-54] Such studies are consistent with a physiologic role for folate receptor-α and the importance of its functioning normally to prevent the development of neural tube defects (NTDs) and neurocristopathies (the latter involve abnormal proliferation and/or migration and/or differentiation of neural crest cells that can result in cleft lip or cleft palate, endocardial cushion defects, and other midline defects).[34,47,52] Indeed, as predicted,[47] brief experimental perturbation of folate receptor-α expression in these neural crest cells within a short window during embryonic development can impair the mitosis and the migration of these cells into the pharyngeal arches, leading to abnormal development of the pharyngeal arch arteries as well as the outflow tract, predisposing to abnormal heart development.[55] Thus congenital heart defects, which occur at a rate of approximately 1% of live births, and NTDs, the second most common congenital neurologic birth defects, are both dependent on the fidelity of folate receptor-α expression, precisely at the right time and in the right cells during early cardiac and neurologic development. The finding of a significant increase in blocking autoantibodies against placental folate receptor-α in women with pregnancy complicated by neural tube defects[56] is a striking human correlate of the experimental studies.[54]

Folate receptor-α is also involved in providing sufficient folate during neuronal regeneration and repair after injury where DNA methylation is also involved.[57]

Folate Receptors and PCFT in Cerebral Folate Transport Across the Choroid Plexus

Folate receptor-α and PCFT are found in the basolateral membranes of the choroid plexus. After folate binds first to folate receptor-α in the choroid plexus, the PCFT assists in transporting folates into the cerebrospinal fluid, which accounts for the normal cerebrospinal fluid–to blood-folate ratio in healthy humans of 3:1. There are documented individuals with abnormalities in either folate receptor-α or PCFT that limit transport of folate to the cerebrospinal fluid. The following are examples: (1) A syndrome of cerebral folate deficiency can arise from a mutation in folate receptor-α, which perturbs folate transport into the cerebrospinal fluid, leading to severe developmental regression in early childhood associated with movement disturbances, epilepsy, and leukodystrophy that is reversed by folinic acid.[58,59] In addition, anti–folate receptor-α antibodies can prevent uptake of folate into the cerebrospinal fluid and lead to either infantile acute cerebral folate deficiency[60] or one of two autism spectrum disorders (Rett syndrome and infantile low-functioning autism with neurologic abnormalities). High doses of oral folinic acid can normalize the cerebrospinal fluid folate and lead to partial or complete clinical recovery in 12 months.[61] (2) Mutations in PCFT result in hereditary folate malabsorption with low to undetectable cerebrospinal fluid folate values,[26,28] which is also evidence that these proteins have a role in mediating folate transport across the choroid plexus.

Renal Retention of Folates (and Cobalamin)

After glomerular filtration, luminal folate binds folate receptor-α in the brush border membranes of proximal renal tubular cells[9] and is internalized rapidly by folate receptor-α–mediated endocytosis; in the low pH of endocytotic vesicles, there is dissociation of folates and slow transport across basolateral membranes into the blood, with recycling of apo-folate receptor-α back to the luminal brush border membrane.[8] A large 550-kDa membrane protein called megalin, which interacts with cubulin and is found in renal proximal epithelial cells, functions as a multiligand receptor for a variety of macromolecules.[62] Megalin also specifically binds to and mediates endocytosis of TCII-cobalamin complexes as well as filtered folate bound to soluble folate-binding proteins in kidney proximal tubules.[63]

INTRACELLULAR ONE-CARBON METABOLISM AND COBALAMIN–FOLATE RELATIONSHIPS

Cellular Folate Retention and One-Carbon Metabolism

Polyglutamylation of folate by the enzyme folylpolyglutamate synthase catalyzes the addition of multiple glutamate equivalents to their γ-carboxyl residue[9] (see Figs. 37-4 and 37-5). In most eukaryotic cells, the pentaglutamate and hexaglutamate forms predominate. Polyglutamylation is needed to retain folates (and antifolates) within cells; in addition, polyglutamylated folates are more efficient substrates for folate-dependent enzymes. In human erythrocytes (red blood cells [RBCs]), folate is accumulated at earlier stages within the marrow by folate receptors[8]; on maturation, more than 90% of $H_4PteGlu_{(n)}$ molecules interact with hemoglobin, which, because of its high capacity, assists in intracellular folate retention.[8] Folate turnover and catabolism in the cytoplasm can be experimentally accelerated by heavy chain ferritin,[64] but the clinical significance is still unclear.

Compartmentalization and Channeling of Folate Metabolism

In an elegant example of conservation of resources, metabolic pathways involving folate are compartmentalized within cells as

multienzyme complexes that shuttle one-carbon units along set paths toward key reactions leading to pyrimidine and purine biosynthesis. The major form of folate transported into the cell is 5-methyl-tetrahydrofolate (5-methyl-THF; 5-methy-H_4PteGlu) (see Fig. 37-5); folic acid, which is formally called pteroylmonoglutamate (PteGlu), requires reduction to tetrahydrofolate by dihydrofolate reductase in a two-step reaction (PteGlu to *dihydro*pteroylglutamate [H_2PteGlu] to *tetrahydro*pteroylglutamate [H_4PteGlu, or THF]). After cellular uptake, 5-methyl-THF must first be converted to THF via methionine synthase (in the methylation cycle). This is a key reaction because THF is the preferred physiologic substrate for folylpolyglutamate synthase, which adds multiple glutamate moieties to THF (see Fig. 37-4). Only then can the polyglutamylated form of THF participate in one-carbon metabolism[41] where it can be converted to either 10-formyl-THF—used in de novo biosynthesis of purines, or to 5,10-methylene-THF—used for synthesis of thymidylate. Moreover, 5,10-methylene-THF and 10-formyl-THF can be interconverted by intermediates (see Fig. 37-5).

Folate metabolism and folate-dependent enzymes are compartmentalized: approximately 40% are in the mitochondrial matrix, 50% in the cytoplasm, and 10% in the nucleus.[65] The mitochondrial compartment *not* shown in Fig. 37-5 contains its complement of folate cofactors, and homologues of the major cytosolic enzymes. For example, cytoplasmic 5-methyl-THF and 5-formyl-THF can enter mitochondria by a mitochondria-specific reduced-folate carrier,[66] whereas SAM, which is also required for mitochondrial methylation reactions, enters mitochondria by a specific transporter.[67] Other one-carbon donors like serine, glycine, dimethylglycine, and sarcosine also enter mitochondria and ultimately generate formate that crosses back into the cytoplasm. In the cytoplasm, C1-THF synthase, a trifunctional enzyme, uses this mitochondria-derived formate with THF to form 10-formyl-THF, which is required for the de novo synthesis of purines (see Fig. 37-5); this enzyme can also catalyze the interconversion of THF, 10-formyl-THF, 5,10-methenyl-THF, and 5,10-methylene-THF. In this way, the continued delivery of mitochondrial formate helps perpetuate cytoplasmic one-carbon metabolism.[65] Another major entry point of one-carbon units into cytoplasmic folate metabolism is through the formation of 5,10-methylene-THF from serine (which is derived from glycolytic intermediates); here the enzyme serine hydroxymethyltransferase catalyzes the addition of carbon 3 from serine to THF to give rise to the key intermediate coenzyme 5,10-methylene-THF.[65] After 5,10-methylene-THF is converted to 5-methyl-THF by the enzyme methylenetetrahydrofolate reductase, it can be used in the methylation cycle that involves methylation of homocysteine via methionine synthase to form methionine and tetrahydrofolate. After 5,10-methylene-THF is converted (via intermediates) to 10-formyl-THF, it can be used for purine nucleotide biosynthesis involving de novo synthesis of purine nucleotides for DNA and RNA. 5,10-Methylene-THF can also be used in the thymidylate cycle via the enzyme thymidylate synthase, which generates thymidylate for DNA synthesis (see Fig. 37-5). Parenthetically, this nuclear one-carbon metabolism compartment is activated during S phase of the cell cycle, following a posttranslational modification of folate-dependent enzymes like thymidylate synthase, serine-hydroxymethyltransferase, and dihydrofolate reductase by specialized small ubiquitin-like modifier (or SUMO) proteins; this modification allows the entry of these sumoylated enzymes into the nucleus[68] so they can generate thymidylate (by converting deoxyuridine monophosphate [dUMP] to deoxythymidine monophosphate [dTMP] close to where DNA is synthesized.

Methylation

After methionine is generated, it can be converted to a methyl donor through its adenosylation to SAM. SAM is a universal donor of methyl groups for critically important biologic methylation reactions involving over 80 proteins, membrane phospholipids, the synthesis of neurotransmitters, RNA, DNA, and histones. Among these, DNA methylation is a major epigenetic mechanism that is central to the regulation of several cellular functions such as gene transcription, chromatin structure, imprinting, development, and genomic instability. DNA is highly methylated in CpG sequences (over 50%); here a methyl group is targeted to the DNA base cytosine in the context of a CpG dinucleotide by DNA methyltransferases. Methylation confers a condensed structure and transcriptional repression, whereas does the opposite. Altered patterns of DNA methylation, particularly hypomethylation involving growth-promoting genes, or hypermethylation of tumor suppressor genes, are popular contemporary themes in our understanding of the epigenetic changes in DNA and the genesis of cancer. In addition, histone hypomethylation can alter gene expression. After these transmethylation reactions that use SAM, the immediate product of these reactions is *S*-adenosylhomocysteine (SAH), which is converted to homocysteine by SAH hydrolase. The SAM to SAH ratio regulates the balance of such cellular methylation reactions.

Dietary folate deficiency can lead to hypomethylation in experimental animals, whereas folate consumption supports normal patterns of methylation. However, analysis in humans has not yielded consistent results, nor has the correlation of folate status and DNA methylation been rigorously studied clinically.

Consequences of Perturbed One-Carbon Metabolism

Methyl-Folate Trapping

Because of the critical role of methylcobalamin for methionine synthase, a deficiency of cobalamin inactivates methionine synthase and results in the accumulation of the substrate 5-methyl-THF; this so-called methyl-folate trap results because the upstream enzyme reaction involving methylenetetrahydrofolate reductase (which converts 5,10-methylene THF to 5-methyl-THF in preparation for the methionine synthase reaction) is irreversible. Because 5-methyl-THF accumulates and cannot be converted to THF, it leaks out of the cell. (This explains why patients with cobalamin deficiency can have normal to high serum folate values). The ensuing intracellular THF deficiency compromises one-carbon metabolism and initiates the pathophysiologic cascade leading to perturbed DNA synthesis and megaloblastosis.

Hyperhomocysteinemia

Similarly, when methionine synthase is inhibited during either cobalamin or folate deficiency, there is a buildup of the thiol amino acid, homocysteine, which can also leak out of the cell and have multiple deleterious effects on the body through a variety of molecular and biochemical pathways. Indeed, measurement of serum homocysteine is a sensitive measure of clinical folate and cobalamin deficiency in nutritional anemias. The clinical significance of hyperhomocysteinemia is discussed later.

Thymidylate Deficiency and Perturbed DNA Synthesis

With either cobalamin or folate deficiency, there will be a net decrease in 5,10-methylene-THF that interrupts the thymidylate synthase–mediated conversion of dUMP to dTMP. (Although salvage pathways for purine synthesis can compensate for reduced generation of purines through one-carbon metabolism, salvage pathways cannot compensate for reduced thymidine). This results in a high dUMP/dTMP ratio and an increase in deoxyuridine triphosphate (dUTP), which can get misincorporated into DNA. At this juncture, an editorial enzyme recognizes this faulty misincorporation and excises dUTP. However, with a continued inadequate supply of deoxythymidine triphosphate (dTTP), there is a failure to repair this break in DNA, leading to several (similar) additional DNA strand breaks that develop

over time; this eventually results in fragmentation of DNA and leakage of DNA fragments out of the cell, leading to megaloblastic changes.

Chromosome and Cell Cycle Defects

Defective DNA synthesis is reflected by numerous chromosomal abnormalities. There is excessive chromosomal elongation with despiralization associated with random breaks and exaggerated centromere constriction, expression of folate-sensitive fragile sites in hematopoietic cells, and reduced biosynthesis, acetylation, and methylation of arginine-rich histone.[8,9] All this leads to perturbation of the cell cycle with an increased proportion of cells in prophase of the mitotic cycle and G_2 that leads to apoptosis of erythroid precursors and anemia.[9]

MORPHOLOGIC EXPRESSION OF MEGALOBLASTOSIS

There is widening disparity in nuclear-cytoplasmic asynchrony as a cobalamin- or folate-deficient cell divides, until the more mature generations of daughter cells die in the marrow or are arrested (as megaloblastic cells) at various stages of the cell cycle.[8] The plethora of bone marrow morphologic changes can lead an untrained observer to the diagnosis of erythroleukemia.[9] All proliferating cells exhibit megaloblastosis, including the luminal epithelial mucosal cells of the entire gastrointestinal tract, cervix, vagina, and uterus.[8] However, megaloblastic changes are most striking in the blood and bone marrow. Ineffective hematopoiesis extends into long bones, and the bone marrow aspirate (which is superior to the biopsy for observing megaloblastosis) exhibits trilineal hypercellularity, especially of the erythroid series. The appearance of exuberant cell proliferation with numerous mitotic figures is misleading because these cells are actually proliferating very slowly (see box on Morphology in Megaloblastosis From Cobalamin and Folate Deficiency Is the Same).

Erythroid hyperplasia reduces the myeloid-to-erythroid ratio from 3:1 to 1:1. Proerythroblasts are not as obviously abnormal as later forms; they may simply be larger (promegaloblasts). Megaloblastic changes are most strikingly displayed in intermediate and orthochromatic stages, which are larger than their normoblastic counterparts. In contrast to the normally dense chromatin of comparable normoblasts, megaloblastic erythroid precursors have an open, finely stippled, reticular, sieve-like pattern (Fig. 37-7). The orthochromatic megaloblast, with its hemoglobinized cytoplasm, continues to retain its large sieve-like immature nucleus, in sharp contrast to the clumped chromatin of orthochromatic normoblasts. The nucleus is often

Morphology in Megaloblastosis From Cobalamin and Folate Deficiency Is the Same

Peripheral Smear
- Increased mean corpuscular volume (MCV) with macro-ovalocytes (up to 14 μm), which is variously associated with anisocytosis and poikilocytosis
- Nuclear hypersegmentation of polymorphonuclear neutrophils (PMNs) (one PMN with six lobes or 5% with five lobes)
- Thrombocytopenia (mild to moderate)
- Leukoerythroblastic morphology (from extramedullary hematopoiesis)

Bone Marrow Aspirate
- General increase in cellularity of all three major hematopoietic elements
- Abnormal erythropoiesis—orthochromatic megaloblasts
- Abnormal leukopoiesis—giant metamyelocytes and "band" forms (pathognomonic), hypersegmented PMNs
- Abnormal megakaryocytopoiesis—pseudo hyperdiploidy

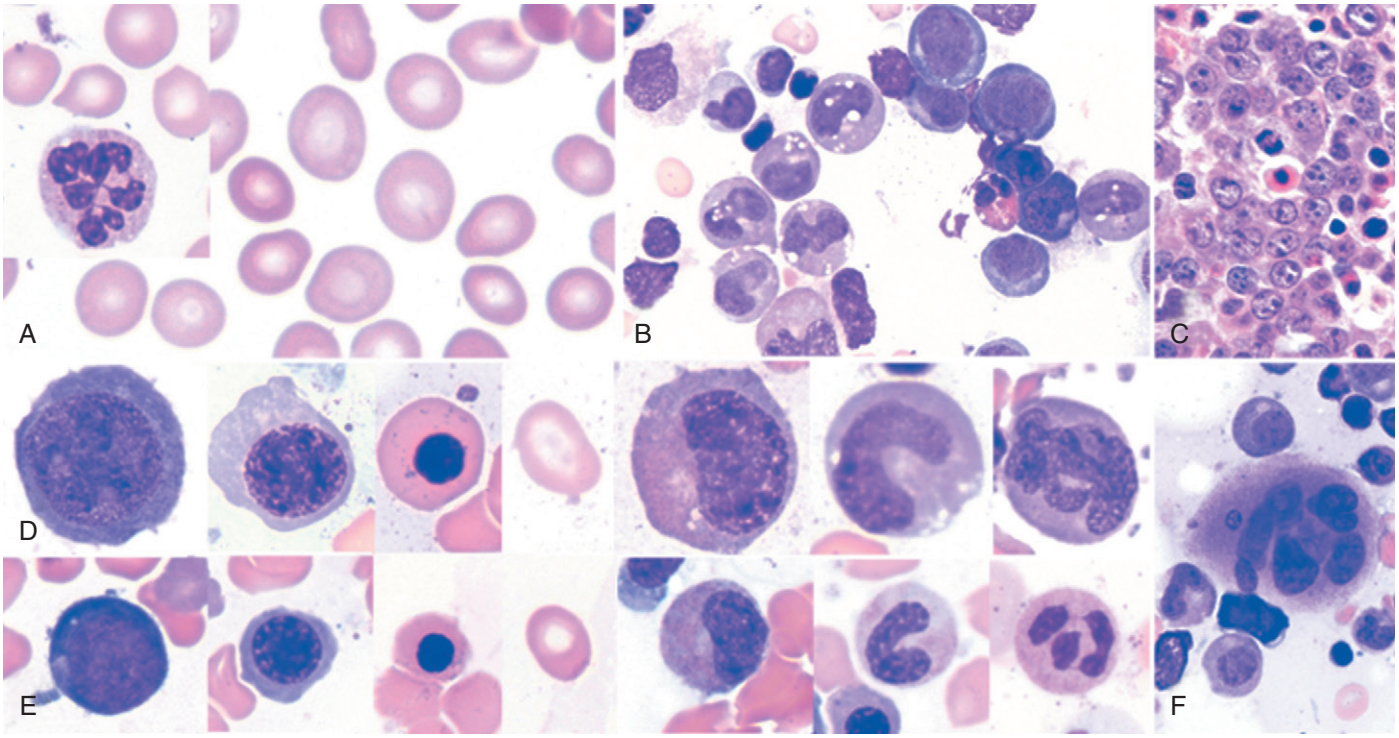

Figure 37-7 MEGALOBLASTIC ANEMIA. The peripheral smear **(A)** exhibits macro-ovalocytosis and hypersegmented polys (inset). The bone marrow aspirate **(B)** shows megaloblastic changes in both granulopoiesis and erythropoiesis. The biopsy **(C)** is hypercellular and shows sheets of immature erythroid precursors with the appearance of a high mitotic rate. These can mimic acute erythroleukemia or even metastatic tumor cells. Details from the cells in the aspirate **(D)** compared with normal hematopoiesis at same magnification **(E)**. Note the giant metamyelocyte and band form. In megaloblastic anemia, megakaryocytes also have nuclear atypica, including abnormal nuclear segmentation **(F)**.

eccentrically placed in these large oval or oblong cells, and lobulation or indentation of nuclei with bizarre karyorrhexis is often seen. In cells destined for the circulation as macro-ovalocytes, the nucleus may occasionally not be completely extruded. Of the potential progeny of proerythroblasts that develop into later megaloblastic forms, 80% to 90% dies in the bone marrow. Marrow macrophages effectively scavenge dead or partially disintegrated megaloblasts. This is the basis for ineffective erythropoiesis (intramedullary hemolysis).

Leukopoiesis is also abnormal. There is an absolute increase in these cells, which are large and have similar sieve-like chromatin. Spectacular giant (20 to 30 μm) metamyelocytes and "band" forms that are often seen are pathognomonic for megaloblastosis (see Fig. 37-7). There may be bizarre nucleoli with small cytoplasmic vacuoles. It is probable that giant metamyelocytes cannot easily traverse marrow sinuses, and their maturation into circulating hypersegmented polymorphonuclear neutrophils (PMNs) is unlikely. Granulation of the cytoplasm remains unaffected.

Megakaryocytes may be normal or increased in numbers and may exhibit additional complexities in megaloblastic expression (see Fig. 37-7). Complex hypersegmentation (i.e., pseudo hyperdiploidy) is associated with liberation of fragments of cytoplasm and giant platelets into the circulation. The net output of platelets is decreased in severe megaloblastosis, and abnormal but reversible platelet dysfunction has been documented.[9]

In early cobalamin or folate deficiency, normoblasts may dominate the marrow with only a few megaloblasts seen. Complete transformation to megaloblastic hematopoiesis is observed in florid cases and is reflected by various degrees of pancytopenia.

The earliest manifestation of megaloblastosis is an increase in mean corpuscular volume (MCV) with macro-ovalocytes (up to 14 μm) (see Fig. 37-7). Because these cells have adequate hemoglobin, the central pallor, which normally occupies about one-third of the cell, is decreased. In severe anemia, poikilocytosis and anisocytosis are evident. Cells containing remnants of DNA (i.e., Howell-Jolly bodies), arginine-rich histone, and nonhemoglobin iron (i.e., Cabot rings) may be observed. Extramedullary megaloblastic hematopoiesis may also result in a leukoerythroblastic picture.

Nuclear hypersegmentation of DNA in PMNs strongly suggests megaloblastosis when associated with macro-ovalocytosis (see Fig. 37-7). Normally less than 5% of PMNs have more than five lobes, and no cells have more than six lobes in the peripheral blood. If megaloblastosis is suspected (greater than 5% PMNs with more than five lobes or a single PMN with more than six lobes), a formal lobe count/PMN (i.e., lobe index) above 3.5 may be obtained.

Ineffective use of iron results in an increased percentage of saturation of transferrin and increased iron stores. If there is associated iron deficiency, the MCV may be normal, and only iron therapy can unmask the megaloblastic manifestations in the peripheral blood. In thalassemia, the entire erythrocyte morphology normally expected in megaloblastosis is masked[8]; however, megaloblastic leukopoiesis is still observed. Significant intramedullary hemolysis (ineffective erythropoiesis) involving more than 90% of megaloblastic precursors is reflected by a lowered absolute reticulocyte count, increased bilirubin (up to 2 mg/dL), decreased haptoglobin, and increased lactate dehydrogenase (LDH) often above 1000 units/mL. There is also a modest decrease in the circulating RBC life span.

Megaloblastosis in rapidly proliferating cells of the gastrointestinal tract leads to a variable degree of morphologic changes and atrophy of luminal epithelial cells. This leads to functional defects, which can include malabsorption of cobalamin and folate in some patients. A vicious cycle whereby megaloblastosis begets more megaloblastosis is established that can be interrupted only by specific therapy with cobalamin or folate.

NEUROLOGIC DYSFUNCTION WITH COBALAMIN DEFICIENCY

Because megaloblastosis due to folate or cobalamin deficiency leads to a functional folate coenzyme deficiency, the morphologic manifestations of both deficiencies are understandably indistinguishable. However, only cobalamin deficiency results in a patchy demyelination process, which is expressed clinically as cerebral abnormalities and subacute combined degeneration of the spinal cord.[8] The precise role of cobalamin in maintaining the integrity of the central nervous system has not been completely defined (see box on Clues for Distinguishing Cobalamin and Folate Deficiencies).

The demyelinating process involves patchy swelling of the myelin sheath followed by its breakdown (demyelination), leading to axonal degeneration. Microscopic foci coalesce with one another, giving the surface of the spinal cord (on cross section) a spongy appearance; later there is secondary Wallerian degeneration of long tracts. Patchy demyelination usually begins in the dorsal columns in the thoracic segments of the spinal cord (Fig. 37-8) and then spreads contiguously to involve corticospinal tracts. These lesions spread throughout the length of the cord and ultimately involve spinothalamic and spinocerebellar tracts. There is also degeneration of the dorsal root ganglia, celiac ganglia, the Meissner plexus, and the Auerbach plexus. Although demyelination may also extend to the white matter of the brain, it is unclear whether the peripheral neuropathy is caused by a distinct lesion or results from spinal cord disease; the clinical manifestations may be extremely varied.[8,9]

Clues for Distinguishing Cobalamin and Folate Deficiencies

Although the megaloblastic manifestations of cobalamin and folate deficiencies are clinically indistinguishable, certain distinct patterns in mode of presentation provide clues to the type and cause of deficiency. In general, the cause of folate deficiency can be found in the patient's recent past (within 6 months), primarily discerned from the history and physical examination. In contrast, the cause of cobalamin deficiency can remain obscure until specific tests to define the cause are carried out. In the past, by the time anemia was symptomatic, more than 80% of patients had neurologic manifestations, and in 50% this led to some incapacity. Perhaps as a result of widespread use of multivitamins containing folic acid among patients and even in the food given livestock in the West, the hematologic expression of cobalamin deficiency is often substantially attenuated, leading to pure neurologic presentations. Studies highlight the apparent inverse correlation between hematologic and neurologic presentations such that in a third of patients with cobalamin deficiency, the earliest signs are often purely neurologic, and symptoms related to paresthesias and diminished proprioception may cause the patient to see the physician. Based on the multiple potential causes (see box on Etiopathophysiologic Classification of Cobalamin Deficiency or box on Etiopathophysiologic Classification of Folate Deficiency), the warning that "what the mind does not know, the eyes do not see" is a caveat that cannot be taken lightly; failure to recognize cobalamin deficiency as the cause of neurologic disease and treatment of cobalamin deficiency with folate, or misdiagnosis of megaloblastosis as erythroleukemia represent significant extremes of deviation from the dictum *primum non nocere.* Areas of overlap in the symptoms of cobalamin or folate deficiency are related to megaloblastosis (i.e., common cardiopulmonary and some gastrointestinal manifestations). Although pure folate deficiency in the alcoholic with thiamine deficiency (i.e., Wernicke encephalopathy) and peripheral neuropathy is almost indistinguishable from and may mimic cobalamin deficiency, the remaining neurologic manifestations are uniquely characteristic of cobalamin deficiency. Folate deficiency in adults has not been unequivocally shown to give rise to neurologic findings. Coexistence of folate deficiency with neurologic disease should prompt investigations to rule out cobalamin and other nutrient deficiencies arising from dietary insufficiency or malabsorption.

Etiopathophysiologic Classification of Cobalamin Deficiency

I. Nutritional cobalamin deficiency (insufficient cobalamin intake)—vegetarians, poverty-imposed near-vegetarians, breastfed infants of mothers with pernicious anemia
II. Abnormal intragastric events (inadequate proteolysis of food cobalamin)—atrophic gastritis, hypochlorhydria, proton pump inhibitors, H_2 blockers
III. Loss/atrophy of gastric oxyntic mucosa (deficient intrinsic factor [IF] molecules)—total or partial gastrectomy, adult and juvenile pernicious anemia, caustic destruction (lye)
IV. Abnormal events in the small bowel lumen
 A. Inadequate pancreatic protease (R factor–cobalamin not degraded, cobalamin not transferred to IF)
 1. Insufficient pancreatic protease—pancreatic insufficiency
 2. Inactivation of pancreatic protease—Zollinger-Ellison syndrome
 B. Usurping of luminal cobalamin (inadequate binding of cobalamin to IF)
 1. By bacteria-stasis syndromes (blind loops, pouches of diverticulosis, strictures, fistulas, anastomosis), impaired bowel motility (scleroderma), hypogammaglobulinemia
 2. By *Diphyllobothrium latum* (fish tapeworm)
V. Disorders of ileal mucosa/IF-cobalamin receptors (IF-cobalamin not bound to IF-cobalamin receptors [cubam receptors])
 A. Diminished or absent cubam receptors—ileal bypass/resection/fistula
 B. Abnormal mucosal architecture/function—tropical/nontropical sprue, Crohn disease, tuberculous ileitis, amyloidosis
 C. Cubam receptor defects—Imerslund-Gräsbeck syndrome
 D. Drug-effects—metformin, cholestyramine, colchicine, neomycin
VI. Disorders of plasma cobalamin transport (transcobalamin [TCII]-cobalamin not delivered to TCII receptors)—congenital TCII deficiency, defective binding of TCII-cobalamin to TCII receptors (rare)
VII. Metabolic disorders (cobalamin not used by cell)
 A. Inborn enzyme errors—cblA to cblG disorders
 B. Acquired disorders (cobalamin inactivated by irreversible oxidation)—nitrous oxide

Etiopathophysiologic Classification of Folate Deficiency

I. Nutritional causes
 A. Decreased dietary intake—poverty and famine, institutionalized individuals (psychiatric/nursing homes)/chronic debilitating disease, prolonged feeding of infants with goat's milk, special slimming diets or food fads (folate-rich foods not consumed), cultural/ethnic cooking techniques (food folate destroyed)
 B. Decreased diet and increased requirements
 1. Physiologic—pregnancy and lactation, prematurity, hyperemesis gravidarum, infancy
 2. Pathologic
 a. Intrinsic hematologic diseases involving hemolysis with compensatory erythropoiesis, abnormal hematopoiesis, or bone marrow infiltration with malignant disease
 b. Dermatologic disease—psoriasis
II. Folate malabsorption
 A. With normal intestinal mucosa
 1. Drugs—sulfasalazine, pyrimethamine, proton pump inhibitors (via inhibition of proton-coupled folate transporter [PCFT])
 2. Hereditary folate malabsorption (mutations in PCFTs) (rare)
 B. With mucosal abnormalities—tropical and nontropical sprue, regional enteritis
III. Defective cerebral spinal fluid folate transport—cerebral folate deficiency (mutation or autoantibodies to folate receptors) (rare)
IV. Inadequate cellular utilization
 A. Folate antagonists (methotrexate)
 B. Hereditary enzyme deficiencies involving folate
V. Drugs (multiple effects on folate metabolism)—alcohol, sulfasalazine, triamterene, pyrimethamine, trimethoprim-sulfamethoxazole, diphenylhydantoin, barbiturates

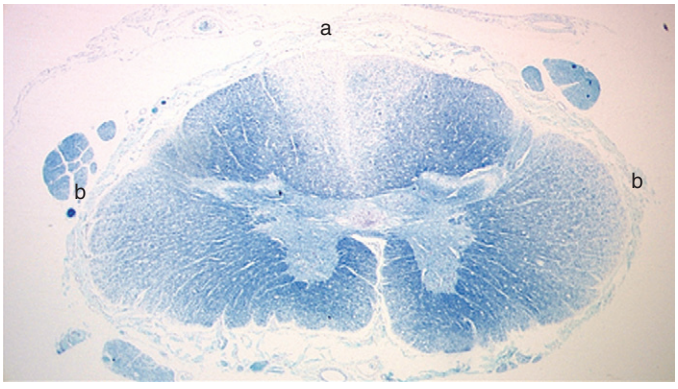

Figure 37-8 SPINAL CORD IN COBALAMIN DEFICIENCY. The cross section of the spinal cord stained with Luxol blue shows demyelination of the dorsal columns *(a)* and early demyelination of the lateral columns *(b)*.

Vegetarians with cobalamin neuropathy in India[69] had cognitive impairment in nearly one-half of 36 patients; it was mostly global with impaired recall and serial sevens (which are useful bedside tests of attention); impaired naming was found among one-quarter of the patients. Nearly one-half had abnormal evoked potential (using the oddball auditory paradigm), which revealed P300 latency that was reversible within 3 months of cobalamin replacement; (in one-fifth P300 was unrecordable). Objective tests to document cobalamin neuropathy[69] include nerve conduction studies and motor- and sensory-evoked potentials,[70,71] visual pathway abnormalities (in 60%[72]), and magnetic resonance imaging (MRI) that shows T2 hyperintensity and atrophy.

Recent studies confirm that among elderly patients with mild cognitive impairment, lowering the homocysteine level by a cocktail that includes cobalamin and folate over 2 years did slow the rate of brain atrophy by almost 30%.[73] This issue is further discussed in Subclinical Cobalamin Deficiency.

Among another cohort of patients with cobalamin neuropathy from the United States, 65% had mild, about 25% had moderate, and about 10% had severe neurologic deficits.[9] Paresthesias or ataxia were most commonly the first symptoms, and diminished vibratory sensation and proprioception in the lower extremities were the most common objective early signs. Although multiple neurologic syndromes were often seen in the same patient, the spectrum of objective signs could include loss of fine or coarse touch, decreased or increased deep tendon reflexes with spasticity or muscle weakness, urinary or fecal incontinence, orthostatic hypotension, amaurosis, dementia, psychosis, or mood disturbances.[9] Overall, although the neurologic deficits were mild in most cases, the severity was judged related to

the duration of symptoms before diagnosis; not unexpectedly, those with the shorter duration of symptoms responded most to appropriate replacement.

OTHER EFFECTS OF COBALAMIN AND FOLATE DEFICIENCY

Cobalamin deficiency more often than folate deficiency can also result in sterility from the effects on the gonads. An unexplained finding is generalized melanin pigmentation that is reversible by specific nutrient replenishment.

SPECTRUM OF CLINICAL PRESENTATIONS WITH COBALAMIN DEFICIENCY

The age-specific presentations with cobalamin deficiency are discussed in Nutritional Cobalamin Deficiency. Classical presentations of nutritional cobalamin deficiency in developing countries are often accompanied by iron deficiency, and among malnourished populations, many will also have folate deficiency. Among vegetarians in developing countries, cases with nutritional cobalamin deficiency may present in the second and third decades with pancytopenia, mild hepatosplenomegaly, fever, and occasionally thrombocytopenic bleeding.[9] Alternatively, a neurologic and psychiatric syndrome may develop with or independent of anemia. Because neuropsychiatric presentations may dominate the clinical picture and the patient may not have anemia, careful review of the peripheral smear may reveal macrocytosis.[9] In over a quarter of patients with cobalamin neuropathy in the United States, there was no reduction in the hematocrit despite neurologic disease, and only a minority of patients had combined hematologic and neurologic disease. Indeed, the higher the hematocrit, the more severe the neurologic disorder! Conversely, anemic patients may have no neurologic deficits, and the level of cobalamin may have no correlation with the existence or severity of neurologic disease.

BIOCHEMICAL INDICATORS OF EVOLVING DEFICIENCY

Early manifestations of negative cobalamin balance are increased serum methylmalonic acid (MMA) and total homocysteine levels (Table 37-1).[9] This occurs when the total cobalamin in serum is still in the low-normal range. Continued negative cobalamin balance leads to an absolute decrease in serum cobalamin level. Normal levels of MMA and homocysteine rule out clinically significant cobalamin deficiency with virtually 100% certainty.[9]

Likewise, metabolic evidence for folate deficiency (i.e., increased serum total homocysteine level) is often found when serum folates are still in the low-normal range.

Laboratory tests are more likely to be accurate when there is a high pretest probability of a particular disease. This can however be more vexing in the case of diagnosis of early cobalamin deficiency when symptoms are subtle, nonspecific, or not yet fully manifest. If there is macrocytosis and cobalamin levels are borderline or just below the normal, unequivocal elevation of MMA will support the diagnosis. However, in elderly patients with anemia, there may be several other causes for anemia, and depending on the population studied, cobalamin deficiency may be only one among several possible causes in the differential diagnosis. This is when a modified therapeutic trial—in which a patient is treated with full doses of both cobalamin and folate for 10 days—and the lack of objective response to cobalamin would effectively rule out cobalamin deficiency as a cause (see box on Modified Therapeutic Trials). Alternatively, attribution of the cause of anemia to cobalamin deficiency would be reasonably confirmed retrospectively if there was evidence for resolution of anemia following such therapy with cobalamin. Although reductions from high serum MMA and homocysteine values to baseline following therapy would also be confirmatory, this is impractical due to the expense of multiple testing.

Table 37-1 Stepwise Approach to the Diagnosis of Cobalamin and Folate Deficiency

MEGALOBLASTIC ANEMIA OR NEUROLOGIC-PSYCHIATRIC MANIFESTATIONS CONSISTENT WITH COBALAMIN DEFICIENCY *PLUS* TEST RESULTS ON SERUM COBALAMIN AND SERUM FOLATE

Cobalamin* (pg/mL)	Folate† (ng/mL)	Provisional Diagnosis	Proceed With Metabolites?‡
>300	>4	Cobalamin or folate deficiency is unlikely	No
<200	>4	Consistent with cobalamin deficiency	No
200-300	>4	Rule out cobalamin deficiency	Yes
>300	<2	Consistent with folate deficiency	No
<200	<2	Consistent with (1) combined cobalamin plus folate deficiency or (2) isolated folate deficiency	Yes
>300	2-4	Consistent with (1) folate deficiency or (2) an anemia unrelated to vitamin deficiency	Yes

TEST RESULTS ON METABOLITES: SERUM METHYLMALONIC ACID AND TOTAL HOMOCYSTEINE

Methylmalonic Acid (Normal, 70-270 nM)	Total Homocysteine (Normal, 5-14 μM)	Diagnosis
Increased	Increased	Cobalamin deficiency confirmed; folate deficiency still possible (i.e., combined cobalamin plus folate deficiency possible)
Normal	Increased	Folate deficiency is likely
Normal	Normal	Cobalamin and folate deficiency is excluded

*Serum cobalamin levels: abnormally low, less than 200 pg/mL; clinically relevant low-normal range, 200 to 300 pg/mL.
†Serum folate levels: abnormally low, less than 2 ng/mL; clinically relevant low-normal range, 2 to 4 ng/mL.
‡Any frozen-over sample from serum folate/cobalamin determination can be subjected to metabolite tests.

BIOCHEMICAL EVALUATION OF COBALAMIN AND FOLATE DEFICIENCIES

Total Serum Homocysteine and Methylmalonic Acid Levels

Cellular nutrient *deficiency* of cobalamin or folate is reflected by decreased intracellular concentrations. Cobalamin deficiency perturbs methionine synthase activity; this results in substrate (homocysteine) buildup and elevated serum levels of homocysteine, which can be measured by a sensitive assay.[9] In addition, cobalamin

Modified Therapeutic Trials

The traditional therapeutic trial using physiologic doses of vitamins (100 mcg of folate or 1 mcg of cobalamin given daily while monitoring the reticulocyte response)[8] has given way to a modified therapeutic trial. Rather than making the diagnosis of a deficiency, *the intention is often to confirm the clinical suspicion that the patient does not have deficiency.* This can be demonstrated by lack of response to full replacement doses of both vitamins (1 mg of folic acid orally for 10 days and 1 mg of cobalamin intramuscularly or subcutaneously daily for 10 days). Clinical scenarios in which such trials may be applicable (after drawing blood for serum cobalamin and folate levels) are as follows:

1. There is a clinical suspicion that the underlying disease is not caused by a vitamin deficiency, but this idea is not supported by results of clinical, morphologic, and biochemical evaluations. Such conditions include anemia with a megaloblastic bone marrow that may be secondary to chemotherapy, myelodysplastic syndromes, or acute leukemia; when time is of the essence in making the diagnosis; when the levels of cobalamin are likely to be falsely abnormal because of these diseases; or when there is underlying dehydration or renal dysfunction that predictably gives falsely high levels of metabolites.
2. In other situations (i.e., pregnancy, acquired immunodeficiency syndrome [AIDS], or alcoholism) with a multifactorial basis for anemia, the response or lack thereof to full replacement doses can eliminate cobalamin or folate deficiency and thereby narrow the (often extensive) differential diagnosis.
3. In instances when severe anemia with megaloblastosis is clinically obvious and so serious that the physician cannot wait for the results of specific tests for deficiency. Full doses of both vitamins are administered, and if there is a response manifested by brisk reticulocytosis by days 5 to 7, retrospective assignment of the deficiency is based on the results of blood samples drawn before beginning the trial.

In all therapeutic trials, if there is no evidence of response within 10 days, bone marrow aspiration is indicated to identify another primary hematologic disease.

deficiency perturbs the activity of methylmalonyl-CoA mutase, which leads to elevated serum MMA levels. Thus homocysteine and MMA are sensitive tests for cobalamin deficiency (see Table 37-1).

Folate deficiency also results in elevated levels of homocysteine due to reduced activity of the methionine synthase–catalyzed reaction.[9] Total homocysteine concentration, which comprises the sum of all homocysteine species in plasma/serum, including free and protein-bound forms, can be measured in plasma or serum.[9,74] In general, plasma levels are slightly lower. Thus an elevation of both homocysteine and MMA, while consistent with cobalamin deficiency, cannot rule out a combined cobalamin and folate deficiency (see Table 37-1); see box on Serum Homocysteine and Methylmalonic Acid Levels in Cobalamin and Folate Deficiencies.

Both homocysteine and MMA levels are elevated in patients with dehydration and renal failure; propionic acid derived from anaerobic fecal bacterial metabolism can also substantially contribute to methylmalonate production.[6] In this setting, the fraction of gut flora contribution to MMA can be reduced by treatment with metronidazole.

The normal value for serum homocysteine is 5.1 to 13.9 μM and serum MMA is 73 to 271 nM, and in general the higher the values, the more severe the clinical abnormalities.[9] However, there is a fairly wide range of "normalcy" in homocysteine values because of age-, creatinine-, gender-, diet-, and race-dependent variables.[74] Basal levels of MMA are usually less than 500 nM, and in renal failure, it rarely

Serum Homocysteine and Methylmalonic Acid Levels in Cobalamin and Folate Deficiencies

The combined use of homocysteine and methylmalonic acid (MMA) levels can differentiate cobalamin from folate deficiency, because most patients with folate deficiency have normal MMA levels, and the remainder have only mild elevations.[9] These two tests are useful diagnostically. The abnormally high levels of metabolites return to normal only when the patient receives replacement with the appropriate (deficient) vitamin. A positive response to cobalamin, documented by falling levels of homocysteine and MMA, is evidence of cobalamin deficiency. Conversely, therapy with folate results in a decrease in the isolated homocysteine level if folate deficiency is present.[9] Indeed, because several variables that are not related to vitamin deficiency (such as age, mild renal dysfunction) can falsely elevate serum homocysteine and MMA levels, if there is ambiguity, proof of vitamin deficiency would require clear-cut demonstration of a reduction in metabolite levels after specific vitamin supplementation.[9,75]

increases by more than 1000 nM.[9] If unseparated blood stands at room temperature, homocysteine levels will *increase* over 4 to 24 hours. Frozen serum (from measurements of serum folate or cobalamin) can be used for serum MMA and homocysteine determinations.

Serum Cobalamin Levels

For the most part, a low serum cobalamin level is an established biochemical indicator of cobalamin deficiency. In general, in patients with clinical cobalamin deficiency and megaloblastic anemia or neurologic disease consistent with cobalamin deficiency, the sensitivity of cobalamin concentration less than 200 pg/mL (or less than 148 pmol/L) exceeds 95%[76]—when the pretest probability is high. However, up to 10% of adults with true cobalamin deficiency have cobalamin values in the low-normal (200 to 300 pg/mL) range and only metabolite testing with homocysteine and MMA will reveal the deficiency (see Table 37-1).

Thus a serum cobalamin concentration is less than 300 pg/mL in 99% of patients with clinical hematologic or neurologic manifestations of cobalamin deficiency,[9] and a cobalamin level of more than 300 pg/mL predicts folate deficiency or another hematologic or neurologic disease (see Table 37-1). However, a low serum cobalamin concentration is not synonymous with cobalamin deficiency, and several associated diseases and conditions can falsely raise or lower cobalamin levels (Table 37-2). Studies have also identified patients with true cobalamin deficiency who have cobalamin levels in the low-normal range. Among 173 unambiguously cobalamin-deficient patients,[9] about 5% had normal cobalamin levels. In addition, a high titer of anti-IF antibody can interfere with the measurement of cobalamin and result in a falsely normal serum cobalamin level.[76]

If the serum cobalamin test is broadly used as a screening test without clinical context, by virtue of the way normalcy is defined, 2.5% of nondeficient individuals will have low levels, which reflects our definition of the lower limit of normal for this test.[9] However, the finding that the same blood sample can give different cobalamin results (one below normal versus one above normal) using different commercial assays is of significant concern.[76] The more recent assays have periodically had such problems, apparently arising from a lack of transparency related to these tests, poor validation using low-cobalamin sera, and poor track record of continuous proficiency testing and tracking of assay performance.[76]

So in the absence of availability of metabolite tests, if there are hematologic or neurologic findings that are consistent with clinical cobalamin deficiency, and the serum cobalamin level is normal or borderline low, it is entirely appropriate to treat as for a cobalamin deficiency. If there is no improvement in hematologic parameters

Table 37-2 Serum Cobalamin: False-Positive and False-Negative Test Results

FALSELY LOW SERUM COBALAMIN IN THE ABSENCE OF TRUE COBALAMIN DEFICIENCY
Folate deficiency (one-third of patients)
Multiple myeloma
TCI deficiency
Megadose vitamin C therapy
FALSELY RAISED COBALAMIN LEVELS IN THE PRESENCE OF A TRUE DEFICIENCY*
Cobalamin binders (TCI and II) increased (e.g., myeloproliferative states, hepatomas, and fibrolamellar hepatic tumors)
TCII-producing macrophages are activated (e.g., autoimmune diseases, monoblastic leukemias and lymphomas)
Release of cobalamin from hepatocytes (e.g., active liver disease)
High serum anti-IF antibody titer

IF, Intrinsic factor; *TC,* transcobalamin.
*Although a low serum cobalamin level is not synonymous with cobalamin deficiency, 5% of patients with true cobalamin deficiency have low-normal cobalamin levels, a potentially serious problem because the patient's underlying cobalamin deficiency will progress if uncorrected.

within a couple of months, provided there are no other conditions that limit a full response to cobalamin (e.g., iron deficiency or underlying thalassemia trait, hypothyroidism, renal disease, infection, alcoholism, or intrinsic hematologic disease in the bone marrow), cobalamin deficiency would be unlikely.

Cobalamin deficiency can falsely raise serum folate by 20% to 30% via methyl-folate trapping. Folate deficiency can also reduce serum cobalamin, but the mechanism is unclear.

Serum Folate Levels

The serum folate level is clinically relevant and widely used. Microbiologic assays for folate, which measure all biologically active forms equally, have been replaced in the West by competitive folate-binding protein assays (from various commercial sources) that are indirect immunoassays, which rely on chemiluminescence methods. These tests are notorious for considerable lack of agreement with one another (see box on Diagnosing Folate Deficiency). Alignment with a new higher-order precision isotope-dilution liquid chromatography–tandem mass spectrometry assay—which demonstrates excellent agreement with the traditional *Lactobacillus casei* method[77]—will allow better standardization of the current competitive folate-binding protein assays.[78]

When negative folate balance continues, hepatic folate stores are depleted in about 4 months.[8] This leads to tissue folate deficiency, which clinically correlates with a decrease in RBC folate (less than 150 ng/mL) by the microbiologic assay.[8] However, current RBC folate tests using different commercial kits have major limitations in sensitivity and specificity and are notoriously unreliable in alcoholics and in pregnancy; furthermore, a reduction of RBC folate also occurs in about 60% of patients with cobalamin deficiency.

The use of red-cell folates as a measure of long-term folate status is valid during clinical trials in which a single kit is used for a cohort of patients; however, it is *not* valuable for routine clinical diagnosis because of the significant variability of performance between different commercial kits and lack of clinical validation. Because of these reasons, the serum folate level, although labile, is a good initial choice.[41]

Other Tests

The use of low holo-transcobalamin II (holo-TCII) levels, a test that was developed to provide information on the extent of saturation of

Diagnosing Folate Deficiency

When combined with a clinical picture of megaloblastic anemia and additional results of cobalamin levels, the serum folate concentration is the cheapest and most useful initial biochemical test to diagnose folate deficiency[9] (see Table 37-1). The serum folate level is highly sensitive to folate intake, and a single hospital meal may normalize it in a patient with true folate deficiency. Rapidly developing nutritional folate deficiency first leads to a decline in the serum folate level below normal (less than 2 ng/mL) in about 3 weeks; it is a sensitive indicator of negative folate balance.[8] However, isolated reduction of serum folate level in the absence of megaloblastosis (i.e., false-positive result) occurs in one-third of hospitalized patients with anorexia, after acute alcohol consumption, during normal pregnancy, and in patients on anticonvulsants[9]; unfortunately, these are the very groups at high risk for folate deficiency and the people who exhibit low serum folate levels when they become folate deficient.[8] Conversely, in 25% to 50% of cases (predominantly alcoholics) with folate-deficient megaloblastosis, the serum folate levels may be low normal or borderline (2 to 4 ng/mL).[9] The serum folate level alone should never dictate therapy. It is important to consider the clinical picture, peripheral smear, and bone marrow morphology and also to rule out underlying cobalamin deficiency.

Summary of the Clinical Usefulness of Tests for Cobalamin and Folate Deficiencies

Within the clinical context of hematologic or neurologic features that suggest the diagnosis of cobalamin deficiency, if the cobalamin levels are suggestive but not definitive, then the MMA and homocysteine tests are an excellent gold standard test to confirm a clinical diagnosis. Patients with clinical cobalamin deficiency usually have MMA values over 1000 nM and homocysteine values that are over 25 μM. The MMA and homocysteine test results are much more sensitive than cobalamin levels and progressively increase much earlier than the drop in cobalamin levels; one or both metabolites was increased in 99.8% of more than 400 patients with proven cobalamin deficiency.[9]

Based on the lower costs of serum cobalamin and folate compared with serum MMA and homocysteine levels, it is recommended (see Table 37-1) to first use the cheaper tests that can assist in the diagnosis of cobalamin and folate deficiency.[9] Clinicians should also restrict use of serum MMA and homocysteine to patients with borderline cobalamin and folate levels; to patients with existing conditions associated with difficulties in the interpretation of test results; to situations in which cobalamin and folate levels are low, when a high MMA level is useful in confirming cobalamin deficiency (rather than attributing the condition to folate deficiency alone); and to patients with clearly low serum levels but for whom there is an alternative explanation for the findings that caused an unusual serum cobalamin level to be obtained (e.g., a diabetic or alcoholic with peripheral neuropathy, an alcoholic with a high MCV and a low serum cobalamin without anemia). In these cases, serum levels of metabolites can assist in the diagnosis of vitamin deficiency.

Diagnostic algorithms consistently stress the value of clinical data to improve the pretest probability of serum cobalamin and serum folate tests.[9] Without detailed clinical information, the combined test results for serum cobalamin, folate, and metabolite (homocysteine and MMA) are not sufficiently unambiguous to diagnose and distinguish cobalamin deficiency from combined cobalamin-plus-folate deficiency. In combined cobalamin-plus-folate deficiency, both vitamins would be needed to restore baseline values, particularly of homocysteine.[9]

serum TCII as an early marker of cobalamin homeostasis,[79] as a surrogate for the Schilling test, or to diagnose cobalamin deficiency in lieu of serum cobalamin values, is still unclear. This test has not yet been clinically validated[76] among groups with various established causes of cobalamin deficiency (to define sensitivity, specificity, and other clinical confounders that can alter results). Although an increase in holo-TCII level has been used to show that cobalamin can be absorbed normally in vegetarians,[80] a cheaper option could be to treat a vegetarian with full replacement doses of cobalamin up front and then move to smaller doses; assuming there are no symptoms, a simple reassessment of cobalamin levels a year later could suffice to ensure that there is no problem. Because even mild renal dysfunction elevates MMA and homocysteine levels, and both the serum cobalamin and holo-TCII rise with only advanced renal disease, they could be useful in mild to moderate renal insufficiency. There is still insufficient clinical data to support the routine use of a urinary MMA test.[9]

PATHOGENESIS OF COBALAMIN DEFICIENCY

Nutritional Cobalamin Deficiency

Vegetarian diets can be classified as lactovegetarian, ovovegetarian, lacto-ovovegetarian, or vegan, respectively, if they include dairy products, eggs, dairy products and eggs, or no animal products at all.[7] Vegan diets have a very low cobalamin content, mandating cobalamin supplementation. Likewise, we now know that asymptomatic lacto-ovovegetarians and lactovegetarians[7,81] and those with low dietary consumption of animal source foods (like dairy products, eggs, or animal meats) must be routinely supplemented with cobalamin.

The fetus is dependent on the mother's cobalamin stores for a sufficient quota of cobalamin at birth; a close correlation exists between low maternal serum- and breast milk–cobalamin concentrations and cobalamin insufficiency in the infant.[82] Therefore when mothers do not consume sufficient amounts of animal-source foods, they themselves are at risk for nutritional cobalamin deficiency, and their infants will have smaller stores of the vitamin at birth.[83] In one study, among breastfed infants 6 to 11 months of age in a middle- to low-income community in New Delhi, one-third had cobalamin deficiency.[84] Thus maternal cobalamin stores exert a strong effect on the infant's cobalamin status[85] for up to 12 months,[86] especially in areas where vegetarianism or poverty-imposed near-vegetarianism is common and prolonged breastfeeding is the norm.[7]

Cobalamin-deficient infants can present with a spectrum of clinical findings, ranging from feeding difficulties and refusal of both breast milk and complementary food by regurgitation (which results in failure to thrive) and motor and social retardation, reflecting a developmental delay. The child is persistently drowsy and rarely sits up or makes eye contact.[87] There may be lemon-tint jaundice with hypotonia, insufficient head control, and delayed spontaneous turning. There can be brownish black areas of hyperpigmentation in the dorsal fingers and toes as well as over the medial thighs, arms, and axillae (which usually resolve within 3 months of therapy). Evidence of megaloblastic anemia may be masked with superimposed iron deficiency. If left untreated, there is growth retardation with reduced height and weight, and reduced head circumference with cranial MRI showing delayed myelination and frontoparietal cortical atrophy in affected infants[88]; these can also be reversed within 3 months of cobalamin replacement. Treatment results in a dramatic increase in alertness and responsiveness of the child, who is now miraculously transformed into a normal child who, within a few days, rolls over spontaneously, makes eye contact with its mother, and is much more interested in the surroundings. Any previous abnormal movements (tremors, chorea, or myoclonus) may regress but transiently return within a few days to affect the face or tongue; however, these will resolve in 2 to 3 months.[89] Cobalamin deficiency often resurfaces during wartime, which invariably leaves women and their infants malnourished.[90]

Infants in the West fed a macrobiotic diet (vegan-like with occasional servings of fish) must be rapidly replenished with cobalamin before switching to a cobalamin-rich diet. Otherwise, up to 20% continue to have low cobalamin status, which can lead to impaired psychomotor functioning well into youth and later adolescence with compromise in faculties related to reasoning, abstract thinking, and learning ability.[91]

Reports on nutritional macrocytic anemia identified cobalamin deficiency as the basis for anemia in up to 50% of cases of Indian children 6 months to 12 years of age, and one-fifth of anemic children 3 months to 3 years of age in an urban Indian slum had cobalamin deficiency based on low serum cobalamin levels. Metabolite testing would have picked up many more asymptomatic cobalamin-deficient children because only anemic children were studied. It is also likely that there is widespread deficiency of iron, folate, and cobalamin among children in India.[7,75] Parallel results come from studies on Guatemalan schoolchildren.[92]

Among schoolchildren in Embu, Kenya, who subsist on restricted monotonous diets,[93,94] there was a similar striking influence of (cobalamin-rich) meat supplementation on performance on tests of fluid intelligence that taps into on-the-spot reasoning and problem-solving ability when compared to controls. This speaks volumes on the sheer inadequacy of these children's diets in most developing countries. The number of affected children in developing countries is staggering: There are tens of millions of breastfed infants, whose mothers have borderline or low cobalamin status, who need aggressive cobalamin supplementation to avoid the risk for permanent neurologic and psychologic stigmata from severe deficiency in infancy.

The prevalence of cobalamin deficiency among older children and adolescents is also high, ranging from 40% to 80% in various communities, because of monotonous diets low in animal-source foods (reflecting poverty-imposed near-vegetarianism). Without any intervention, these adolescent girls with low to borderline cobalamin stores fall next in line as a new generation of prospective mothers who will give birth to infants with low or borderline cobalamin stores. And so this vicious cycle continues from one generation to another.

Recent longitudinal studies from the West among women who apparently consume a balanced nonvegetarian diet confirm that pregnancy places an additional stress on the mother's cobalamin stores and can lead to metabolic evidence of cobalamin deficiency.[95-97] This can negatively affect their breastfed infants' cobalamin status at 6 weeks; indeed, over two-thirds of Norwegian infants of otherwise healthy mothers had a metabolic profile consistent with cobalamin deficiency, which reverted to normal after cobalamin replenishment.[96,97] This emphasizes that many more breastfed infants may need cobalamin supplements early in life than previously realized. Such studies raise new questions as to whether the optimal intake of cobalamin in women should be much higher than 2.4 mcg/day, perhaps increased to between 4 and 7 mcg/day.[98]

There is dual significance of cobalamin deficiency for mothers and their infants: Inadequate cobalamin status among women is associated with adverse pregnancy outcomes, including NTDs,[99,100] preterm births,[101] intrauterine growth-retardation,[102,103] and even recurrent miscarriage.[104] For the infant, there is a critical time in prenatal and early postnatal neurodevelopment when sufficient folate and cobalamin is required for the proper formation of neurologic circuits; indeed, perturbation of neurodevelopment can give rise to subtle changes that can manifest in behavioral abnormalities long after the folate and cobalamin deficiency is reversed.

Pregnant adolescents are more generally likely than adults to consume energy-dense, micronutrient-poor diets containing suboptimal folate[105] and thereby experience adverse pregnancy outcomes with small-for-gestational-age babies.[106] And as more young girls recognize that adoption of vegetarian diets can help them to keep slim—a not uncommon practice among high-profile Hollywood celebrities and supermodels—cobalamin deficiency could be on the rise even in Western countries.

Intragastric Events Leading to Cobalamin Malabsorption

Inadequate Dissociation of Cobalamin From Food Protein

Dietary cobalamin is bioavailable only after proteolytic digestion of food by gastric acid and pepsin. Failure to release cobalamin from food protein can lead to food-cobalamin malabsorption and frank cobalamin deficiency despite the presence of IF.[9]

Congenital Intrinsic Factor Deficiency

Congenital IF deficiency due to mutations in gastric IF,[107] resulting in complete loss of IF, can be transmitted as an autosomal recessive trait and expressed in homozygotes by the age of 2 years as severe megaloblastic anemia (less than 100 cases reported).[108] Dysfunctional IF may lead to only a mild abnormality in binding to cobalamin and result in a delayed presentation into the second decade.

Loss or Atrophy of Gastric Oxyntic Mucosa

IF deficiency, which arises from atrophy of gastric parietal (oxyntic) mucosal cells, can be caused by total or partial gastrectomy; by autoimmune destruction, as observed in adult Addisonian pernicious anemia or, rarely, in a similar disease in children (juvenile pernicious anemia); and after destruction of gastric mucosa by caustic (lye) ingestion.

Total gastrectomy invariably leads to cobalamin deficiency in about 5 years (range, 2 to 10 years). This condition is often associated with iron deficiency (leading to a dimorphic anemia),[8] warranting routine cobalamin and iron replacement prophylactically.

Cobalamin deficiency can eventually develop in 10% to 20% of patients 8 years after partial gastrectomy; a minority (about 5%) develop frank clinical manifestations of cobalamin deficiency with megaloblastic anemia. The cause is multifactorial, and contributing factors include decreased IF secretion, hypochlorhydria, intestinal bacterial overgrowth of cobalamin-consuming organisms, and associated iron deficiency. The degree of cobalamin deficiency depends on the size of the remaining gastric remnant. It is more common in Bilroth II than in Bilroth I surgery, and in subtotal than in partial gastrectomy. Morbidly obese patients treated surgically with gastric bypass also have more food-cobalamin malabsorption than patients treated with vertical banded gastroplasty.[9] Even after laparoscopic Roux-en-Y gastric bypass, and despite multivitamin supplementation, iron deficiency was seen in one-half of patients and cobalamin deficiency seen in one-quarter at 3 years[109]; therefore these patients probably need higher oral cobalamin (or addition of parenteral) therapy.

Absent Intrinsic Factor Secretion and Pernicious Anemia

A common cause of cobalamin malabsorption is pernicious anemia, an autoimmune disease in which the fundamental defect is atrophy of the gastric (parietal cell) oxyntic mucosa that eventually leads to the complete absence of IF and HCl secretion (Fig. 37-9). The autoimmune gastritis (leading to chronic atrophic gastritis) associated with pernicious anemia involves the fundus and body of the stomach, and the histologic appearance of the gastric mucosa (infiltration with plasma cells and lymphocytes) is strongly reminiscent of the autoimmune type of lesions. Because cobalamin is absorbed only by binding to IF and uptake by ileal IF-cobalamin receptors, the net consequence is severe cobalamin malabsorption leading to cobalamin deficiency.

The annual incidence of pernicious anemia is approximately 25 new cases per 100,000 persons older than 40 years. Although the average age of onset is about 60 years, pernicious anemia is no respecter of age, race, or ethnic origin. The predisposition to developing pernicious anemia may have a genetic basis, but neither the mode of inheritance nor the initiating events or primary mechanism is precisely understood. There is a positive family history for about 30% of patients, among whom the risk for familial pernicious anemia is 20 times as high as in the general population; about 20% of siblings of patients are projected to develop pernicious anemia by the age of 90 years. And pernicious anemia has developed concordantly in identical twins.

There is a significant association of pernicious anemia with other autoimmune diseases,[8] including Graves disease (30%), Hashimoto thyroiditis (11%), vitiligo (8%), Addison disease, idiopathic hypoparathyroidism, primary ovarian failure, myasthenia gravis, type 1 diabetes mellitus, and adult hypogammaglobulinemia.[8,9]

Anti-IF antibodies are found in the serum of about 60% of patients with pernicious anemia and in the gastric juice of 75%; about 90% of patients with pernicious anemia have anti-IF antibodies in serum or gastric juice.[8] Among African American women with pernicious anemia, 95% have high titers of anti-IF antibodies. Similar IF antibodies are quite rare in the general population. Thus anti-IF antibodies are highly specific and confirmatory for pernicious anemia, but their absence does not rule out the condition. Despite the high incidence of anti–parietal cell immunoglobulin G (IgG) antibodies in the serum of 90% of patients with pernicious anemia, this test is nonspecific and not useful clinically to diagnose pernicious anemia.

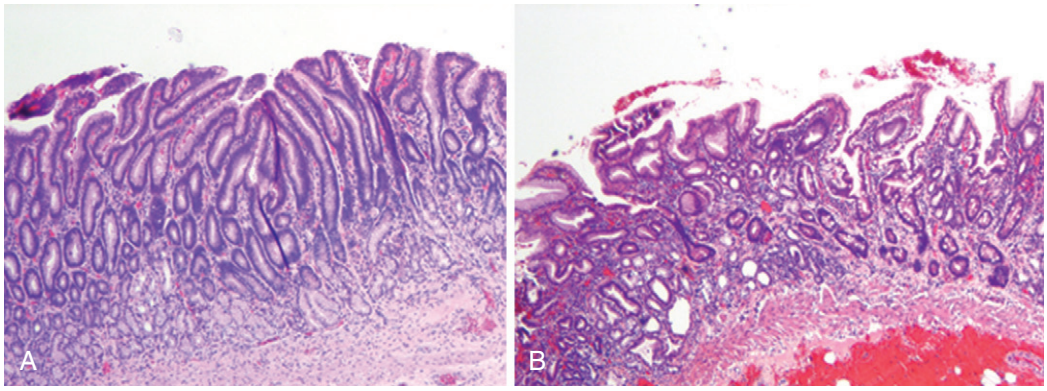

Figure 37-9 HISTOLOGIC FEATURES OF STOMACH IN PERNICIOUS ANEMIA COMPARED TO NORMAL. The normal gastric mucosa **(A)** is contrasted to that seen in pernicious anemia **(B)**, in which there is atrophy of gastric glands, intestinal metaplasia with goblet cells, and loss of parietal cells (not visible at this magnification).

Juvenile pernicious anemia can manifest in the second decade with severe cobalamin deficiency in conjunction with many of the associated endocrinopathies and autoantibodies observed in adults.[8]

Undiagnosed pernicious anemia is common among free-living elderly persons (over 60 years of age)[9] who have only minimal clinical manifestations of cobalamin deficiency (i.e., 1.9% of the Southern California survey population had unrecognized and untreated pernicious anemia). The prevalence was 2.7% in women and 1.4% in men; but 4.3% of the African American women and 4.0% of the white women had pernicious anemia.

Abnormal Events in the Small Bowel Lumen

Insufficient Pancreatic Protease

About 30% of patients with severe pancreatic insufficiency fail to degrade R proteins, which will lead to impaired transfer of cobalamin from R protein to IF. Pancreatic extract will normalize cobalamin malabsorption.[8]

Inactivation of Pancreatic Protease

Pancreatic protease can be inactivated by massive gastric hypersecretion arising from a gastrinoma in Zollinger-Ellison syndrome.[8] The continued low pH of the luminal contents reaching the ileum may also perturb interaction of the IF-cobalamin complex with IF-cobalamin receptors (which requires a pH above 5.4).

Usurpation of Luminal Cobalamin

The near-sterile condition of the small bowel is maintained by a combination of the mechanical cleansing action of peristalsis and the chemical action of gastric acid. Disorders conducive to relative stasis, impaired motility, and hypogammaglobulinemia are predisposing factors that favor colonization by bacteria. Many of these bacteria can take up free cobalamin, but not IF-bound cobalamin. However, if colonization extends proximally to the locus at which IF and cobalamin interact, significant cobalamin may be usurped before it can bind to IF.[8] This cobalamin malabsorption can be corrected to some extent by a 7- to 10-day course of antibiotic therapy; definitive surgical correction may be indicated if the patient has significant symptoms (weight loss and diarrhea) that are only partially relieved by antibiotics. The malabsorption of food-cobalamin in patients with atrophic gastritis has also been normalized with antibiotics, thereby incriminating bacterial usurpation of food cobalamin at a very proximal level.[9]

Approximately 3% of individuals infested with the fish tapeworm *Diphyllobothrium latum,* which avidly usurps cobalamin for growth,[8] can develop frank cobalamin deficiency. Humans become infected when they eat partially cooked or raw fish containing plerocercoids, which develop into adult worms in the jejunum in about 6 weeks, growing to a length of 10 m, with up to 4000 proglottids[8]; when these worms lay eggs, the life cycle is repeated. After ova have been identified in the stools, expulsion of the worms by praziquantel (10 to 20 mg/kg as a single dose taken orally) and cobalamin replenishment is curative.

Disorders of Ileal Intrinsic Factor–Cobalamin Receptors or Mucosa

Absence of Intrinsic Factor–Cobalamin Receptors

The distal ileum has the greatest density of IF-cobalamin receptors. Disease or removal of only 1 to 2 feet of terminal ileum by resection or bypass reduces ileal IF-cobalamin receptor numbers for interaction with IF-cobalamin, resulting in cobalamin malabsorption.[8,9]

Defective Intrinsic Factor–Cobalamin Receptors or Post–Intrinsic Factor–Cobalamin Receptor Defects

Imerslund-Gräsbeck syndrome is a term used collectively for a heterogeneous group of congenital (autosomal recessive) disorders in children arising from biallelic mutations (in 80% of cases) involving either the cubulin (CUBN) or amnionless (AMN) genes that constitute the functional IF-cobalamin receptor (i.e., cubam).[110-112] This results in selective cobalamin malabsorption. Children present between 3 and 10 years of age with megaloblastic anemias and neurologic presentations with low serum cobalamin levels associated with mild, persistent, benign proteinuria (in 90% of cases). Because cubam also participates in the renal tubular absorption of several other proteins, this is the basis for proteinuria found in Imerslund-Gräsbeck syndrome. Diagnosis requires analysis of mutational status of gastric IF, CUBN and AMN genes.[113]

Drug-Induced Defects

Long term use of H_2 antagonists or proton pump inhibitors may interfere with the handover of food-cobalamin to IF, especially in those with preexisting borderline cobalamin stores. Long-term treatment with metformin can interfere with IF-cobalamin binding to ileal cubam receptors[114] and progressively increases the risk for cobalamin deficiency over time.[115] In some individuals the serum cobalamin will dip down to such sufficiently low levels by 3 to 4 years that many physicians would consider cobalamin replacement. Cumulative metformin dose has been correlated strongly with clinically worsening diabetic peripheral neuropathy and increase in MMA and homocysteine levels.[116] Therefore if a patient is not regularly taking at least 1.2 g/day of calcium (to reverse the metformin effect on IF-cobalamin interaction with the cubam receptor[114]), a prudent approach would be to preemptively screen for cobalamin deficiency after about 3 to 4 years of metformin therapy; additional confirmation of metabolic evidence of cobalamin deficiency (elevated MMA) can reasonably trigger replacement therapy with cobalamin. Other drugs (e.g., cholestyramine, colchicine, neomycin) probably also impair transepithelial transport of cobalamin.[8]

Disorders of Plasma Cobalamin Transport

Polymorphism or absence of TCI can be associated with low cobalamin levels, but the MMA and homocysteine levels are normal. By contrast, either deficiency or defective TCII can present with megaloblastic anemia in infancy; this can be associated with normal cobalamin levels (because TCI, which binds over 75% of serum cobalamin is normal). However, there will be metabolic evidence of cobalamin deficiency that can be reversed by daily or biweekly injections of 1 mg of cobalamin, which ensures passive cobalamin delivery into cells. Mutations in the gene for the TCII receptor have also been identified.[117]

Disorders of Intracellular Cobalamin Use

Congenital Metabolic Defects of Cobalamin Metabolism: Cobalamin Mutants A to G

Given the multitude of chaperones or transporters involved in escorting cobalamin intracellularly to their destination to function as coenzymes for methionine synthase and methylmalonyl-CoA mutase, it is not difficult to envision that there would invariably be inborn errors of cobalamin metabolism where one of these escorts or transporters is missing. The combination of megaloblastic anemia with increased levels of homocysteine or MMA, or both, in serum and urine despite normal cobalamin and folate levels should suggest an inborn error of

cobalamin metabolism.[9,108] The inherited defects of cobalamin use (see Fig. 37-3) are heterogeneous and are empirically defined as cobalamin mutations A to G (cblA to cblG).[118]

Among these conditions, the cblC metabolic disease warrants special mention because it is the most common of these inborn errors of metabolism (more than 400 patients have been reported). Patients with cblC are usually diagnosed within the first year of life. These infants must be differentiated from those with nutritional cobalamin deficiency who could have similar clinical features. Some patients with cblC disorder may have a later onset of presentation, even in the fourth decade of life, with neurologic manifestations, cognitive and psychiatric problems, and megaloblastic anemia with a *normal* cobalamin level but *high* homocysteine and MMA levels.[119] Patients suspected of having an inborn error of metabolism should be evaluated by specialized laboratories, such as the McGill University laboratory of Professor David Rosenblatt—a premier diagnostic center.[118]

Functional Cobalamin Deficiency After Nitrous Oxide Exposure

Nitrous oxide (N_2O) inactivates coenzyme forms of cobalamin by oxidizing the fully reduced cob(I)alamin to cob(III)alamin; this results in a state of functional intracellular cobalamin deficiency. This syndrome was first identified in patients with tetanus given nitrous oxide for up to 6 days.[8] Subsequently, persons exposed to nitrous oxide for open heart surgery and through chronic (surreptitious, accidental, or occupational) exposure have been recognized as being at high risk for developing megaloblastosis and cobalamin-deficient neuromyelopathy.[8] The slang word for recreational use of nitrous oxide is *nanging;* capsules that are used for making whipped cream are a cheap and easy source of nitrous oxide in the community. Megaloblastosis develops within 24 hours and lasts less than 1 week after a single exposure. The neurologic syndrome is usually seen with chronic intermittent exposure. Severe neurologic deficits have been reported after prolonged intraoperative exposure to nitrous oxide in patients with unsuspected cobalamin deficiency.[9]

Subclinical Cobalamin Deficiency

The issue of subclinical cobalamin deficiency has been a vexing problem and a semantic dilemma. Many elderly persons may have various symptoms consistent with aging (including fatigue, cognitive changes, lower quality-of-life measures, and subtle symptoms of neuropathy) that cannot be directly attributed to cobalamin deficiency, despite the fact that these very symptoms are often seen in symptomatic cobalamin deficiency; often this triggers testing with a serum cobalamin test, and a borderline result generates a new set of problems, including the need to label this entity and thereby make clinical decisions.

Although dependent on the population studied, the frequency of (silent) subclinical cobalamin deficiency in the United States is likely to be 10 times higher than classical (overt) cobalamin deficiency that is found in 1% to 2% of the population. This is best shown in populations in India, where many individuals had low cobalamin levels and no apparent symptoms of clinical hematologic or neurologic evidence of cobalamin deficiency.[7] Today, with the ability to demonstrate an increase in metabolites (i.e., serum homocysteine and MMA test results), many of these individuals (with elevated metabolite test values) would be characterized as having subclinical cobalamin deficiency, provided they had no subtle cognitive abnormalities (discussed further later). If such cognitive tests were positive, such patients would have to be reclassified as having overt clinical cobalamin deficiency.

A cutoff value of 148 pmol/L (less than 200 pg/mL) is consistent with 3 standard deviations (SDs), and using this cutoff, about 3% to 5% of patients with clinical cobalamin deficiency will be missed.[76] Of course, those patients with low cobalamin values without clinical or metabolic evidence of cobalamin deficiency clearly do not have deficiency. In this context, abnormal MMA values that are less than 800 nM are considered borderline and probably not of clinical significance because true cobalamin deficiency results in values that are more than 1000 nM and more often in the thousands of nM.

Other patients may have low-normal cobalamin levels that spontaneously revert to normal, or minimally fluctuate above or below the cutoff value, or remain stable without change over many years. For these patients, the history and physical findings can identify existing disease conditions and drugs that may predispose to cobalamin deficiency, and follow-up is an important mandate. In this cohort, unless the MMA is above 1000 nM on initial testing, the cobalamin can be repeated a year later, and without further change, repeated testing would be required only if new symptoms attributable to cobalamin deficiency were to develop in the future.

However, in other patients, on subsequent testing, the previously equivocal cobalamin level will have dropped further and the MMA result will rise well over 1000 nM, supporting the likelihood of a more ominous progression toward frank cobalamin deficiency with potential for developing overt clinical symptoms.

It should be noted that the literature is ambiguous about how to manage the entity of subclinical cobalamin deficiency, defined when there is biochemical evidence for cobalamin deficiency—reflected by a low cobalamin value (and increased MMA and homocysteine) but without overt clinical manifestations. Although some experts do not feel obliged to treat, preferring to wait until there are overt symptoms, others feel ethically bound to treat even without overt clinical manifestations. Indeed, the issue of "overt clinical manifestations" poses a new problem because some patients with low cobalamin levels plus elevated metabolites with cognitive impairment (when formally tested) can respond to replacement therapy. And upon improvement, these individuals would then have to be recategorized (in retrospect) as having had overt clinical manifestations. On the other hand, patients without cognitive abnormalities (upon formal testing) would be categorized as having subclinical cobalamin deficiency and not require cobalamin replacement. Therefore the central issue here is whether the patient has had formal cognitive testing. However, not all clinicians can reliably diagnose cognitive abnormalities in the clinic; therefore formal cognition testing requires specialized neurocognitive studies, like P300 testing. Thus unless we do formal cognitive testing for patients with low cobalamin and elevated metabolites, we will not know with certainty that a given patient does, or does not, have subclinical versus clinical evidence of cobalamin deficiency. Parenthetically, because cognitive changes are best measured using specialized tests, a related question is whether such testing belongs to the realm of clinical medicine; a strong case can be made that this does, in the same way a computed tomographic (CT) scan or positron emission tomographic (PET) scan is used today, and with far less risk to the patient.

Should all such patients with low cobalamin and high MMA values be subjected to formal P300 cognition testing and/or MRI for brain atrophy[73] to confirm that they do not have organic disease? The answer depends on whether any intervention can make a difference. Because there was a slowing of the rate of brain atrophy among a cohort of patients with mild cobalamin impairment who were given a cocktail of B vitamins, including cobalamin,[73] then using the principle of *primum non nocere,* any biochemical evidence of cobalamin deficiency with cognitive or MRI-imaging evidence of abnormality should, in theory, be characterized as overt disease that warrants cobalamin replacement therapy.

Assuming that sending all patients with metabolic evidence of cobalamin deficiency for MRI imaging or formal neurocognitive P300 testing would be too expensive or impractical, are there heuristic methods that can be used to ensure a satisfactory outcome for these patients? A minimalist approach with substantially reduced costs would be to preemptively treat all patients with low cobalamin and high MMA values on the assumption that we were potentially treating (some or many) patients with *cobalamin-responsive* cognitive dysfunction and thereby possibly preventing their morbidity, whereas those without cognitive dysfunction or MRI abnormalities would not be harmed. In this context, after replenishing potentially depleted

cobalamin stores with parenteral cobalamin therapy, oral supplementation for 4 to 6 months on and 4 to 6 months off may afford an adequate cobalamin status in most patients[120] as an alternative to continuous therapy. A key factor is the cost of cobalamin (and the lack of side effects associated with cobalamin therapy); for example, parenteral cobalamin, which can be purchased on the Internet for $15 for each 10 mg/10 mL vial, would last a year after replenishing stores. The additional purchase of 30-gauge ½-inch insulin U100 syringes for monthly subcutaneous injection would be less cost than even generic tablets of 1 mg taken daily.

In the case of evolving metformin-induced cobalamin deficiency,[115,116] an even stronger case can be made to prevent harm and to therefore treat early documented biochemical evidence of cobalamin deficiency on the basis that this is not going to get better with continued intake of a valuable drug for diabetes.

Some experts have suggested that randomized trials are needed to define the best approach to manage such patients with subclinical cobalamin deficiency.[76] However, the new information on preventing brain atrophy with combined B vitamins[73] could force many institutional review boards and/or institutional research ethics committees to issue a mandate that all patients with subclinical cobalamin deficiency who were to enter such trials (to define the natural history of this condition) should have prior clearance of normal cognitive function and evidence of no brain atrophy by MRI imaging. However, this would still not obviate the need for these tests for the majority of patients with subclinical cobalamin deficiency if a watch-and-wait approach were to be adopted. Hence the better (and cheaper) option may be that which empirically treats all patients using the principle of beneficence and thereby not harming those with cobalamin-reversible brain disease.[73]

Table 37-3 Clinical Conditions Not to Be Confused With Megaloblastosis

MACROCYTOSIS* WITHOUT MEGALOBLASTOSIS†
Reticulocytosis
Liver disease
Aplastic anemia
Myelodysplastic syndromes (especially 5q-)
Multiple myeloma
Hypoxemia
Smokers
SPURIOUS INCREASES IN MCV WITHOUT MACRO-OVALOCYTOSIS‡
Cold agglutinin disease
Marked hyperglycemia
Leukocytosis
Older individuals

MCV, Mean corpuscular volume.
*The central pallor that normally occupies about one-third of the normal red blood cell is decreased in macro-ovalocytes. This contrasts with the finding of thin macrocytes, in which the central pallor is increased.
†Although megaloblastosis implies that a bone marrow test has been performed, with the addition of highly sensitive tests for the specific diagnosis of cobalamin and folate deficiency, the need for a bone marrow test is often dictated by the urgency to make the diagnosis.
‡When the Coulter counter readings of a high MCV are not confirmed by looking at the peripheral smear.

PATHOGENESIS OF FOLATE DEFICIENCY

Folate deficiency is usually recognized in the course of certain clinical presentations that predispose to negative folate balance and subsequent deficiency. It is instructive therefore to conceptualize cellular folate deficiency as arising from etiologic categories of decreased supply (i.e., reduced intake, absorption, transport, or use) or increased requirement (i.e., metabolic consumption, destruction, or excretion). However, in the same patient more than one mechanism may result in net folate deficiency. The precise contribution of one mechanism over the other is often not obvious, and specific tests to define each mechanism are not routinely available for clinical use. Thus the clinical context is especially important. Megaloblastic manifestations of folate deficiency (Table 37-5) are discussed within the context of the history and physical examination (discussed later). Cases of neuropathy in adults attributed to folate deficiency are rarely encountered; when they are, the possibility of alcoholism with thiamine deficiency must be considered. In any case, every patient with neuropathy, myelopathy, or psychiatric manifestations associated with megaloblastosis must be investigated in detail to rule out cobalamin deficiency. Gastrointestinal megaloblastosis begets further folate malabsorption, which propagates a vicious cycle of folate deficiency in the short term and cobalamin deficiency in the long term. With the exception of drug-induced defects or inborn errors of folate metabolism that result in decreased use of intracellular folates, all causes, irrespective of mechanism, result in reduced net delivery of folates to normal proliferating cells.

Nutritional Causes of Folate Deficiency

The body stores of folate are adequate for only about 4 months.[8] Individuals who are chronically in negative folate balance may only require a brief "nudge"—from superimposition of an associated illness that leads to hemolysis, anorexia, or folate malabsorption—to "tip" them into frank folate deficiency. The incidence of folate deficiency varies from country to country and even within regions in the same country. This is highly influenced by the economic status and ethnic diet where cooking and choice of foods vary from region to region. For example, in Benin, central Africa, the prevalence of folate deficiency anemia was 20%, and in Zimbabwe, 30% had low folate levels, whereas in Sudan it was nearly 60%.[121] In Sri Lanka, one-half of schoolchildren had low-folate status, but less than 1% had folate deficiency in Thailand, which likely relates to the abundant consumption of greens and meats by Thais. Even in the United States, before folate fortification of food, about 20% of the population had low-folate status, and in Venezuela, 30% had low-folate status before such fortification. Decreased availability of folate-rich foods (in winter, after natural disasters, or during the wet season in central Africa), poverty, various cultural or ethnic diets (consisting of maize, rice, or well-cooked beans and vegetables), and cooking techniques that destroy food folate, coupled with the anorexia that accompanies chronic illnesses, are just a few of the reasons for rapid development of folate deficiency.[8,9]

In Western countries food faddism, alcoholism, or unbalanced slimming diets usually lead to decreased folate intake in young to middle-age individuals.[8] Edentulous or infirm persons or neglected older adults who are too ill to prepare their meals, as well as psychiatric patients, are particularly at risk for nutritional folate deficiency[8] (see box on Etiopathophysiologic Classification of Folate Deficiency).

Pregnancy and Infancy

Pregnancy and lactation are associated with significantly higher folate requirements (over 400 mcg/day) for growth of the fetus, placenta, breast, and other maternal tissues.[122] Folate requirement increases throughout pregnancy and is maximal near term. There is also increased urinary loss of folate in pregnancy (about 14 mcg/day versus approximately 4.2 mcg/day in nonpregnant women) because of a lower renal threshold. Poor preparation for pregnancy—with a poorly balanced diet and preexisting multifactorial nutritional anemia that remains unaddressed—is a major factor accounting for serious pregnancy complications and adverse birth outcomes. Therefore additional folate during pregnancy is required to prevent both pregnancy complications (preeclampsia, placental abruption or infarctions, recurrent miscarriage) and poor pregnancy outcomes (preterm

delivery, NTDs, congenital heart defects, and intrauterine growth retardation).[123] Low-folate status associated with short interpregnancy intervals or twin pregnancies also predisposes to preterm births.[124,125] All this demand for folate must somehow be met by increased folate intake.

However, the vast majority (over 90%) of pregnant women in resource-poor countries consume less than the estimated average requirement of folate[126]; in addition, a substantial number also consume less than optimum amounts of several other minerals, such as iron, and micronutrients, including cobalamin, as noted earlier. For example, studies on women from groups with low socioeconomic status from North India[24,25] have estimated that the daily intake of folic acid ranged between 75 mcg and 167 mcg, which is far lower than the 400 mcg/day required to prevent birth defects. This is simple to remedy. When given daily or even twice weekly, the combination of iron (100 mg elemental iron) and folic acid (0.5 mg) has been shown to significantly improve several cognitive abilities of schoolgirls in India,[87] which renders them better prepared for pregnancy in the future. This is all the more important because of results from experimental studies designed to define the influence of gestational folate deficiency on the fetus (discussed later). Thus pregnancy with poor folate intake is the most common cause of megaloblastic anemia in the world.

As noted earlier, the placenta has a large number of folate receptors,[44] which facilitate binding and transport of folates to the developing fetus.[44] Preferential delivery of folate to the fetus can cause or aggravate folate deficiency in the mother.[8] This is observed clinically when a mother with severe folate deficiency gives birth to a baby who has normal folate stores.[43]

The rapidly proliferating tissues in children also have an absolute requirement for exogenously supplied folate. Although human milk can maintain folate balance in breastfed infants, the breast milk content of folate is low when the mother's folate status is poor.

Before the advent of routine folate supplementation during pregnancy, the incidence of megaloblastic marrows in the United States, Canada, and the United Kingdom during late pregnancy was about 25%, but in South India, it was about 55%.[8] Folate deficiency is eight times as high in twin pregnancies. Multiparity (multiple frequent pregnancies with a prolonged state of negative folate balance) and hyperemesis gravidarum commonly lead to folate deficiency. Because the anemia of pregnancy is most frequently caused by iron deficiency, combined iron and folate deficiency (dimorphic anemia) is the more frequent clinical presentation. Increased use of folates by the newborn leads to a drop in serum folate levels by about 6 weeks of age. This drop is exaggerated in premature infants (who have feeding difficulties, infection, or hemolytic disease leading to pure folate deficiency); hence supplementation is routine for them.[8]

Folates and Neurodevelopment

All inborn errors of folate metabolism, which result in reduced folate availability to the developing brain, give rise to mental retardation and related mental health problems. The fetal brain is dependent on sufficient provision of maternal folate during embryogenesis. Thus it has been predicted that, under conditions where maternal folate deficiency can compromise the delivery of folate to the developing fetal brain, and depending on the degree of deficiency, there could be a spectrum of neurologic abnormalities; this could range from full-blown NTDs to more subtle changes that manifest in childhood as behavioral abnormalities.[47,48,127] Because routine folate supplementation is now the norm for women, we must rely on experimental studies in animals to clarify the pathologic effects of folate deficiency in pregnancy. Such studies[48] indicate that folate deficiency will significantly compromise early pregnancy outcomes (including the rates of pregnancy, rate of implantation, and effects on the number of live births). Even lesser degrees of folate deficiency to only one-third of optimum dietary folate for 2 months before and throughout gestation in dams—which coincidentally mimics the extent of insufficient dietary folate availability among women in vast areas of Northern India[44]—also resulted in subtle histologic aberrations and defects during murine fetal development.[48] These included increased apoptotic cell loss involving nearly every organ and fine architectural anomalies, as well as adverse influences on fetal brain development and unexpectedly profound abnormalities in the white matter, reflecting perturbed neuronal development.[48] Surprisingly, despite postnatal folate replenishment, these mice exhibited an anxiety phenotype in adulthood.[128] The latter studies indicate a new paradigm for the developmental origin of neuropsychiatric disease that points to poor maternal folate nutrition during pregnancy. These data also suggest the existence of a sensitive window during fetal neurodevelopment when folate deficiency dysregulates the expression of certain genes and/or proteins, which leads to the imprinting of abnormal neural circuits in utero that predispose to anxiety in adulthood. In concordance with these studies in mice, a recent prospective cohort human study has reported that lower maternal folate status in early pregnancy was associated with childhood hyperactivity/inattention and peer problems in early childhood.[129] The associations between low maternal folate and head circumference at birth[129] are similar to murine studies in which a net reduction in the number of cells (by approximately 20%) in the brains of murine fetuses that experienced gestational folate deficiency[48,127] was observed; this increased brain cell loss was due to apoptosis arising from megaloblastosis of folate-deficient cells during development.

There is additional clinical support for a relationship between suboptimal folate delivery to the developing fetal brain and abnormal behavior. For example, 18-month-old children of mothers who took folate supplements had less "internalizing" patterns of behavior (emotionally reactive, anxious/depressed, somatic complaints, withdrawn) and less "externalizing" syndromes involving attention problems and aggressive behavior compared to offspring of women who did not take folate supplements.[130] Thus it appears that we are likely peering through the mist into a new field whereby nutritional sensitivity during fetal neurodevelopment predisposes to neuropsychiatric illness!

The long-lasting benefit to the offspring of women who take iron and folic acid during the early stages of pregnancy appears to be a consistent theme; in Nepalese women, such supplementation provided significant benefits to the proper neurodevelopment of their babies in utero.[131] Children of these women exhibited improved brain function, manifest by improvement in both general intellectual ability and some aspects of executive functions as well as fine motor skills when tested at ages 7 to 9 years. Although this clinical study was unable to assign whether iron or folic acid was the more important, there is sufficient supporting experimental evidence in the literature for both being critically important. Indeed, these human parallels to murine studies are consistent with the Barker hypothesis on developmental origins of disease. Finally, there is also evidence to suggest that suboptimal folate intake that leads to low-folate status during adolescence can affect cognition, which will negatively affect academic achievements, quite independent of socioeconomic status.[132] And another recent large observational study has also identified that maternal use of folic acid supplements in early pregnancy was associated with a reduced risk for severe language delay in children at age 3 years.[133] Collectively these clinical and experimental studies strongly support the importance of folate during neurodevelopment.

The new finding that homocysteinylated-hnRNP-E1 orchestrates a nutrition-sensitive posttranscriptional RNA operon that includes mRNAs that are important for the integrity of myelin and neuronal intermediate neurofilament-middle molecular mass proteins, as well as tyrosine hydroxylase, which generates dopamine and norepinephrine, provides insight into how folate and cobalamin deficiency during pregnancy can influence neurodevelopment.[39,48,128] Indeed, the activation of multiple members of the hnRNP family by high intracellular homocysteine—via folate or cobalamin deficiency in pregnancy—may in fact activate several such nutrition-sensitive posttranscriptional RNA operons, which, acting together in concert as a higher-order nutrition-sensitive (homocysteine-responsive) posttranscriptional RNA regulon, would lead to the modulation of several diverse mRNAs that exert a profound effect on fetal neurodevelopment.[39]

Folate-Responsive Neural Tube Defects and Neurocristopathies

NTDs are the most common major congenital malformation of the central nervous system. They arise from disturbances in neurulation that involve incomplete closure of neural tissues, leading to major midline defects. The neural tube, which begins as a tiny ribbon of tissue, normally folds inward to form a tube by the 28th day after conception. Thus NTDs originate in the first month of pregnancy (before many women know they are pregnant). The expression of folate receptors on embryonic neural tube and neural crest cells as well as the critical bursts of proliferative activity and the need for folate to support cell proliferation have been discussed earlier. Thus it is critical for a woman to have enough folic acid in her body before conception (periconceptionally) to ensure sufficient availability for the embryo. Anencephaly and spina bifida, the commonest NTDs, are important factors in fetal mortality (Fig. 37-10). Worldwide, the risk in the general population ranges from less than 1 to 9 cases per 1000 births; for example, a recent population-based study in the least-developed area in India identified that the incidence of NTDs was up to 8.21 per 1000 live births, which is among the highest worldwide.[134] Landmark studies have established the preventive role of periconceptional folates in both the *recurrence* of NTD (using folic acid 4000 mcg/day) and the *first occurrence* of NTD (using folic acid 400 mcg/day). Of significance, the greatest protection by folates occurs in those regions with the highest rates of NTDs. Conversely, the use of folic acid antagonists (trimethoprim, triamterene, carbamazepine, phenytoin, phenobarbital, and primidone) during pregnancy increases the risk for these birth defects by twofold.[135]

Because 50% of pregnancies in the United States and elsewhere are unplanned and compliance with taking folic supplements to prevent NTD is only at about 50%, a consensus developed that fortification of food with folic acid in the United States was the best way to improve overall folate status in women at risk for NTD occurrence. By January 1998, fortification of foods (i.e., rice, flour, pasta, macaroni, breads, and cake with folic acid at 140 mcg/100 g of food) was part of American law. This level was chosen to ensure that women of childbearing age would have an increase in folic acid intake of at least 100 mcg a day, which is about 25% of the recommended daily intake. Subsequent evaluation has clearly demonstrated that fortification of food with folic acid has had multiple salutatory effects during human development and that major congenital abnormalities can be prevented.[122] Table 37-4 shows several documented collateral benefits identified through population-based studies.

There remain questions about the effectiveness of the folic acid fortification program for women in the 15- to 35-year-old age-group

Reduction in age-related (sensorineural) hearing loss[141,*]
Reduction in first occurrence of NTDs[142,143]
Reduction in recurrence of NTDs[144,*]
Reduction in phenytoin-induced gingival hyperplasia[145,*]
BENEFICIAL EFFECTS OF FOLIC ACID FORTIFICATION OF FOOD (POPULATION-BASED STUDIES)
Reduction in NTDs[146-148] (anencephaly, spina bifida, encephalocele, meningocele, iniencephaly)
Reduction in cleft lip with or without cleft palate[149]
Reduction in severe congenital heart disease[149,150] (endocardial cushion defects, conotruncal defects)
Reduction in congenital pyloric stenosis, stenosis of the ureteropelvic junction, limb reduction defects[149]
Reduction in stroke mortality[151]
Decreased risk for preterm births,[152] low birth weight, and small-for-gestational-age babies

NTD, Neural tube defect.
*Paper with randomized controlled trial data; grade A studies.

in preventing NTDs. Because of an incomplete knowledge base among some women[9,153] and their tendency to consume low-carbohydrate foods (which are the very foods that are fortified), there is continued concern that this group is still not getting adequate amounts of dietary folate. This is the basis for recommendations to continue to educate women of childbearing age to take folate supplements at 400 mcg/day (beyond what they are already receiving through folate fortification of food).

Indeed, a recent large U.S. study suggests that preconceptional folate supplements (1 year or longer)—*over and above* the folate present in folate-fortified foods—reduced spontaneous preterm delivery between 20 to 28 weeks by 70%, with 50% reduction between 28 and 32 weeks.[152] However, because folate fortification of food—which was operative 2 years before this study also likely afforded small reductions in preterm delivery, the magnitude of benefit by folic acid[152] is likely underestimated.[123] Hence all women capable of becoming pregnant, particularly those women in the periconceptional period, are advised to consume 400 mcg folate daily from folic acid supplements, folate-fortified foods, or both.

Contrary to the assertion in the American Dietetic Association's position paper on vegetarianism,[154] there is an insufficient body of evidence to confidently assert that women in the United States of childbearing age who consume a balanced vegetarian diet with abundant green leafy vegetables will obtain sufficient folate and therefore not be at risk for giving birth to babies with NTDs. Until robust evidence from clinical trials is available to support this association's position paper,[154] all women who are vegetarians must take cobalamin and folate supplements.

Folates and Intrinsic Hematologic Disease

Because folate is necessary for hematopoiesis, folate requirements are increased when there is significant compensatory erythropoiesis in response to peripheral RBC destruction, abnormal hematopoiesis, or infiltration by abnormal cells in marrow. The recognition that folate deficiency developing in hemolytic disorders can lead to an acute aplastic crisis has led to routine prophylactic administration of folate. An unexpected increase in transfusional requirement or a fall in platelets can also suggest folate deficiency.[8] The case of a patient with sickle cell disease on long-term folate who developed pernicious anemia and presented with neuropsychiatric dysfunction is a valuable reminder that those on folate prophylaxis need periodic follow-up for symptoms and signs of supervening cobalamin deficiency.[155]

Folate Malabsorption With Normal Intestinal Mucosa

Hereditary Folate Malabsorption

Hereditary folate malabsorption, which is due to a mutation in PCFT, is associated with inability to transport folate across the intestine and into the brain, resulting in low serum and cerebrospinal fluid folate values with megaloblastic anemia, chronic diarrhea, and neurodevelopmental defects with seizures and mental retardation; this syndrome responds to high-dose parenteral folinic acid that bypasses and overcomes the transport defects. Affected patients can also present with a syndrome of reversible subacute combined immunodeficiency syndrome with hypogammaglobulinemia and recurrent infections.[156] If diagnosed early in infancy, hereditary folate malabsorption responds well to parenteral 5-formyltetrahydofolate and can allow normal development into adulthood.[157]

Folate Malabsorption With Intestinal Mucosal Abnormalities

Tropical Sprue

Residents of, and visitors to, endemic areas in the tropics can acquire a disorder characterized by small intestinal malabsorption.[8] Generalized, nonspecific small bowel malabsorption leads to a wide spectrum of clinical manifestations arising from defective absorption of fat, carbohydrate, albumin, calcium, folate, and in later stages, cobalamin.[8] There is abrupt onset of explosive, intermittent, or continuous diarrhea, abdominal distention, and pain, associated with anorexia, vomiting, and extreme fatigue. Stools are fluid or semisolid and frequently contain mucus and blood. This stage is followed weeks to months later by nutrient deficiency. Later, as steatorrhea continues, megaloblastosis dominates the clinical picture. In the short term, malabsorption leads to folate deficiency, but later in the chronic (longer than 3 years) phase of the disease, cobalamin malabsorption contributes additional clinical manifestations of cobalamin neuropathy.[8] There is some degree of villous atrophy and loss of intestinal functional surface. Although less severe than in nontropical sprue, it is more extensive, involving the entire small intestine.

After investigations for associated iron, cobalamin, and folate deficiencies, therapy with folate and a broad-spectrum antibiotic (e.g., tetracycline) is indicated together with symptomatic treatment of diarrhea and vomiting; fluid, mineral, and electrolyte imbalance; and other associated nutritional deficiencies.[8]

The endemic nature of this disorder in the tropics (and in certain households)[8] and the beneficial response to antibiotics all suggest an infectious origin. However, the dramatic response to folate, which is curative in the first year in about 60% of cases (this cure is cited to be almost diagnostic of the disease), has not been explained.[8] It is unlikely that pure folate deficiency is the primary cause, because nutritional folate deficiency does not result in tropical sprue; the clinical response to antibiotics suggests a close interplay between a pathogenic infectious agent, endogenous flora, and the folate status of the enterocyte.

Nontropical Sprue

Nontropical sprue (i.e., celiac disease, gluten-induced enteropathy) is the most common cause of intestinal malabsorption in temperate zones. It results from a possibly inherited sensitivity to gluten (a glutamine-rich protein found in wheat, barley, rye, and other grains) and a related substance, gliadin.[8] The intestinal lesion (i.e., villous atrophy with hypertrophied crypts and lymphocytic and plasma cell infiltrate of the lamina propria) is more florid than that seen in tropical sprue but occurs to a greater extent in the proximal small intestine with relative ileal sparing; as a result, cobalamin malabsorption is less common. The consequences of malabsorption are otherwise the same. Patients present between the ages of 30 and 50 years with intermittent or persistent diarrhea (abrupt in 20%), weight loss, abdominal distention with discomfort, glossitis, and megaloblastic anemia. Iron deficiency may also be prominent. Diagnosis is established by demonstration of sensitive and specific serum antiendomysial antibodies IgA type or anti–tissue transglutaminase antibodies, malabsorption, and jejunal biopsy. The megaloblastosis responds well to folate therapy.[8]

Regional Enteritis and Other Small Intestinal Disorders

The distal small intestine is involved in 80% of individuals with Crohn disease, but folate is efficiently absorbed in other more proximal areas. Only with extensive involvement or fistulas do these patients develop folate deficiency. Even in this case, the blood picture is more that of an iron deficiency or anemia of chronic disease. Frank, pure megaloblastic anemia occurs rarely enough in this setting to suggest another cause for folate or cobalamin malabsorption.

Cerebral Folate Deficiency

Infants fed cow's milk can develop autoantibodies to milk folate-binding proteins, which have close homology to folate receptors.[32,158] These anti–folate receptor antibodies can bind folate receptors in the choroid plexus and block folate receptor–mediated folate transport across the cerebrospinal fluid to induce cerebral folate deficiency[60] or one of two autism spectrum disorders.[61]

Infantile-onset cerebral folate deficiency[159,160] usually develops 4 to 6 months after birth and is characterized by agitation, insomnia, delayed development with deceleration of head growth, psychomotor retardation, cerebellar ataxia, pyramidal tract signs in the legs, dyskinesias (such as choreoathetosis and ballismus), a severe polyneuropathy, and in some cases, seizures. Untreated, central visual disturbances can become manifest and lead to optic atrophy and blindness by the third year.

Affected children have normal serum folate but low cerebrospinal fluid folate levels. The folate receptor autoantibody titer decreases with restriction of bovine milk intake but promptly increases upon rechallenge. Cerebral folate deficiency responds to high doses of folinic acid and a bovine milk–free diet.[61]

Anti–folate receptor antibodies are also associated with neural tube defects,[161-163] infertility,[164] and orofacial clefts[165]; however, more information is required to confidently assign causality with these conditions.

Polymorphisms and Inborn Errors of Folate Metabolism

Several genetic polymorphisms involve genes that participate in one-carbon metabolism. These genetic polymorphisms merely reflect variants that are more frequent than the expected 1% allelic variation that could be found in any population. Whereas some polymorphisms impinge on normal physiology of folate and explain abnormal laboratory levels of folate, cobalamin, or metabolites, others may redistribute folate toward thymidylate synthesis and be "DNA protective." Predictably, two or more polymorphisms in the same individual (a combined heterozygote) can be associated with an increased risk for certain congenital diseases in offspring such as Down syndrome[166] or other birth defects. However, because disease association is not equivalent to disease causation, much more study is required to strengthen such relationships. A listing of the spectrum of these polymorphisms can be found in specialized texts.[167] Excellent reviews of these and other inborn errors of folate metabolism are available.[9,108]

MEGALOBLASTIC ANEMIA NOT CAUSED BY FOLATE OR COBALAMIN DEFICIENCY

Several chemotherapeutic agents (e.g., antimetabolites, alkylating agents) kill malignant cells primarily by interfering with DNA synthesis; megaloblastosis is therefore an expected side effect. Hereditary orotic aciduria usually manifests in the first year of life because of a deficiency or absence of enzymes that convert orotic acid to uridine monophosphate via orotidine monophosphate. The net cellular deficiency of uridine monophosphate leads to perturbed synthesis of DNA as well as RNA[8] (see box on Miscellaneous Megaloblastic Anemias Not Caused by Cobalamin or Folate Deficiency).

CLINICAL PRESENTATIONS AND EVALUATION FOR FOLATE AND COBALAMIN DEFICIENCY

Clinical presentations and evaluations for folate and cobalamin deficiency are shown in Table 37-5.

The Interview

The patient's general demeanor and answers to questions may reveal a blunted affect with evidence of depression, irritability, forgetfulness, and sleep deprivation (common in pure folate deficiency). Alternatively, cobalamin deficiency may present with paranoid ideation, dementia, cognitive dysfunction, delusions, or lack of energy manifested by slowed responses. Hallucinations or even obtundation may preclude obtaining an adequate history. The family may indicate the progressive evolution of a marked personality change and may be able to help trace the evolution of symptoms and deviations from the time when the patient was last well. Intermittent therapy with multivitamins, liver pills, or injections (often given by a well-meaning family member or unregistered practitioner) is a common quick fix in many cultures. Family members are a good source for details on the patient's

Miscellaneous Megaloblastic Anemias Not Caused by Cobalamin or Folate Deficiency

I. Congenital disorders of deoxyribonucleic acid (DNA) synthesis
 A. Orotic aciduria
 B. Lesch-Nyhan syndrome
 C. Congenital dyserythropoietic anemia
II. Acquired disorders of DNA synthesis
 A. Deficiency—thiamine-responsive megaloblastic anemia (thiamine transporter 1 mutation)
 B. Erythroleukemia, refractory sideroblastic anemias
 C. Drugs—all antineoplastic drugs that inhibit DNA synthesis (including antinucleosides used against human immunodeficiency virus [HIV] and other viruses), alcohol

Table 37-5 Similarities of Clinical Manifestations and Megaloblastic Sequelae of Folate and Cobalamin Deficiency*

System	Manifestations
Hematologic	Pancytopenia with megaloblastic marrow
Cardiopulmonary	Congestive heart failure
Gastrointestinal	Beefy-red tongue and added stigmata of broad-spectrum malabsorption in folate deficiency†
Dermatologic	Melanin pigmentation and premature graying
Genital	Cervical or uterine dysplasia
Reproductive	Infertility or sterility
Psychiatric	Depressed affect and cognitive dysfunction
Neuropsychiatric‡	Unique to cobalamin deficiency with cerebral, myelopathic, or peripheral neuropathic disturbances, including optic and autonomic nerve dysfunction

*However, the neurologic spectrum of dysfunction in cobalamin deficiency is distinct. Inadequate hemoglobinization (from inadequate iron stores or globin synthesis) can mask the expected erythroid megaloblastic morphologic findings in the bone marrow and peripheral smear, and only specific therapy (i.e., iron) can unmask classic megaloblastic manifestations (i.e., masked megaloblastosis). Megaloblastic leukopoiesis is unchanged.
†If folate deficiency is uncorrected for 2 to 3 years, cobalamin deficiency will supervene.
‡Dorsal tract involvement is earliest manifestation in more than 70% of patients with cobalamin deficiency. Neuropsychiatric manifestations are not associated with megaloblastosis in up to 30% of patients.

dietary habits (food faddism, vegetarianism, alcohol intake) and family history of medical problems (blood diseases, gluten sensitivity, autoimmune diseases).

A medical history of epilepsy or alcoholism with seizure disorder (anticonvulsant therapy) is important. Rarely, patients with autoimmune hemolytic anemias may be lost to follow-up and return with acute aplastic crises when they run out of folate. A surgical history of total or partial gastrectomy, anastomosis, fistula, or bowel resection can reveal the potential for perturbation of physiologic absorption (loss of IF, bypassing or loss of absorptive surface, blind loop syndromes). Surreptitious or accidental inhalation of nitrous oxide in an occupational setting (dental or anesthesiology professionals) and deliberate inhalation of nitrous oxide (nanging) using cartridges attached to whipped cream dispensers or visits to "houses of laughter," where nitrous oxide can be inhaled for a small fee can be revealed only on direct questioning. Visits to tropical countries and the development of intermittent episodic diarrhea may give a clue to tropical sprue; prolonged (over 3 years) chronic gastrointestinal symptoms followed by insidious development of neurologic problems predicts a combined (folate followed by cobalamin) deficiency (see box on Drugs That Perturb Folate Metabolism).

Systemic review of symptoms may range from none (i.e., incidental increased MCV or PMN hypersegmentation) to severe (i.e., unstable angina from severe anemia). With slow development of anemia, the patient often does not develop cardiopulmonary symptoms until there is a 50% reduction in hemoglobin concentration, which leads to dyspnea on exertion, palpitation, and generalized fatigue or lethargy. Only when the hemoglobin concentration is below 5 g/dL does the patient develop dyspnea at rest and angina on modest exertion or even at rest. Congestive heart failure is heralded by pedal edema, nocturia, orthopnea, and tender hepatomegaly.

Upper gastrointestinal symptoms with anorexia associated with intrinsic gastrointestinal disease or anemia with heart failure must be distinguished from symptoms due to glossitis. The latter may lead to inability to wear dentures, tolerate hot drinks or spicy foods because of burning, and even odynophagia, which may compromise further food intake (seen in cobalamin and folate deficiencies). The patient may volunteer that glossitis is relieved by multivitamin ingestion. Weight loss in cobalamin deficiency is not as severe as in folate deficiency arising from intrinsic gastrointestinal disease. Episodic or chronic diarrhea with steatorrhea is commonly caused by tropical sprue, although it may be brought on by gluten-containing foods. Although these symptoms may be accompanied by abdominal pain, pain in the absence of diarrhea could be caused by tabetic crisis (vomiting, abdominal rigidity, absence of leukocytosis, or fever) accompanying spinothalamic involvement in cobalamin-deficient myelopathy.

The patient with pernicious anemia may have two or three semisolid bowel movements per day; although this may be construed as

Drugs That Perturb Folate Metabolism

Ethanol. Although beer has a higher folate content than other alcoholic beverages, alcoholism may lead to neglect of healthy dietary practices in favor of alcohol. Patients who have one nutritious meal each day tend to stave off the eventual development of folate deficiency. Alcohol consumption leads to a relatively rapid (2- to 4-day) fall in serum folate levels. Excess alcohol consumption is possibly the most common cause of folate deficiency in the United States.[8]

Trimethoprim and *pyrimethamine* bind to bacterial and parasitic dihydrofolate reductase with much greater affinity than to human dihydrofolate reductase, but patients with underlying folate deficiency appear to be more susceptible to the effects of these drugs. The megaloblastosis can be reversed by folinic acid (5-formyl-tetrahydrofolate [5-formyl-THF]; leucovorin).

Methotrexate binds with high affinity to human dihydrofolate reductase and leads to trapping of folate as a metabolically inert form (dihydrofolate). This leads to a true depletion of THF within hours and consequently to functional deficiency of 5,10-methylene-THF and reduced thymidylate synthesis. Although megaloblastosis can develop rapidly, the toxic effects of methotrexate can be avoided by rescue with 5-formyl-THF (leucovorin).

Sulfasalazine produces megaloblastosis in up to two-thirds of patients taking full doses (over 2 g/day) by decreasing absorption of folates and induction of Heinz body hemolytic anemia (i.e., increased requirements).

Anticonvulsants can induce NTD, and consensus guidelines have stressed the importance of ensuring that pregnant women[9] and children[168-171] with epilepsy be prescribed folates together with anticonvulsants. Whereas folates protect against spontaneous abortion,[172] folic acid supplementation of women receiving antiepileptic drugs, which are known to interfere with folate absorption, also led to a significant reduction of spontaneous abortion.[173] Now there is new clinical data on phenytoin-induced gingival hyperplasia, which is a cosmetically undesirable side effect that affects a large percentage of patients, usually between 2 and 6 months of initiating therapy. A recent randomized controlled trial among children 6 to 15 years of age who were initiated on phenytoin has provided incontrovertible evidence that taking folic acid 0.5 mg daily can largely prevent phenytoin-induced gingival hyperplasia[145]; whereas 88% in the placebo group developed gingival hyperplasia, only 21% in the folic acid group developed this side effect. The data from this paper provides more "ammunition" to encourage young women on antiepileptic drugs to keep taking folic acid to prevent them from getting cosmetically unsightly gingival hyperplasia (particularly if reducing the risk for having a baby with NTD is too nebulous a concept for them). The only caveat is that before initiating long-term folic acid supplements, the cobalamin status must be normalized.

Although *antineoplastics* and *antiretroviral antinucleosides* such as azidothymidine lead to megaloblastosis, the temporal sequence and investigations to rule out cobalamin or folate deficiency should easily lead to a correct causal assignment.

a normal pattern, it may represent a change since the last time the patient was well. Constipation may be related to obstipation arising from involvement of the Meissner plexus and the Auerbach plexus within the gastrointestinal tract. Similarly, incipient loss of bladder or bowel control due to cobalamin myelopathy may present with urgency or nocturia.

In contrast to musculoskeletal symptoms (arthralgia or frank arthritis) of autoimmune diseases, nocturnal cramps or pain in upper and lower extremities may indicate spinothalamic tract involvement. Hypoparathyroidism or systemic lupus erythematosus, alone or associated with pernicious anemia, leads to significant overlap of cerebral, musculoskeletal, and neurologic presentations.

Review of skin symptoms may elicit a history of increased diffuse or blotchy generalized brownish skin pigmentation, especially of nail beds and skin creases. This is common in cobalamin and folate deficiency; associated vitiligo suggests autoimmune disease.

Although symptoms related to neurologic dysfunction may be volunteered, a complete detailed questionnaire should be formulated during the interview. Questions should be directed to perversions in taste or smell, decreased visual acuity, changes in color vision, and eye pain (neuritis), tinnitus, or headache. Dizziness with orthostatic hypotension and "blacking out" may be related to severe anemia. Vertigo or difficulty in walking in the dark (loss of proprioception and position sense), difficulty in ambulation (which may feel like "walking on cotton wool"), stiffness of extremities (corticospinal tracts), or ataxia (spinocerebellar tracts) may be indicative of a serious cobalamin myelopathy. Early symptoms are symmetrical tingling ("pins and needles"), extending from the tips of the toes to a glove and stocking distribution in later stages. "Burning feet" syndrome, or more commonly, complaints of difficulty in performing simple tasks such as buttoning clothes, may also be a presenting symptom. When loss of bladder and bowel control brings the patient to the physician, advanced neurologic dysfunction is invariably present.

Genitourinary symptoms such as impotence or recurrent cystitis from bladder dysfunction can suggest cobalamin neuropathy. Multiple pregnancies with short intervals between delivery and conception predispose to a high risk for overt folate deficiency and contribute to fetal growth restriction in babies (cobalamin deficiency is more often associated with infertility).

The Physical Examination

Physical examination may reveal different features in well-nourished patients (cobalamin-deficient vegetarians or pernicious anemia) and poorly nourished (folate-deficient) individuals. The latter show evidence of significant weight loss or other stigmata of multiple deficiencies due to "broad-spectrum" malabsorption. Associated deficiency of vitamins A, D, and K and protein-calorie malnutrition may give rise to angular cheilosis, bleeding mucous membranes, dermatitis, osteomalacia, and chronic infections. Various degrees of pallor with lemon-tint icterus (i.e., a combination of pallor and icterus best observed in fair-skinned individuals) are common features of megaloblastosis.

When anemia is severe, the patient may have a low-grade fever. The skin may reveal a diffuse, brownish pigmentation or abnormal blotchy tanning.[174] A macular hyperpigmentation with follicular accentuation may be observed in the axilla and groin; hyperpigmentation can also involve the dorsal acral distal interphalyngeal joints and a reticular pigmentation in the mid–upper back can develop slowly over a year (but resolves within 2 months of cobalamin replacement).[174] Special emphasis should be given to pigmentation of skin creases and nail beds. (Mucous membrane pigmentation is not observed, in contrast to Addison disease.) Premature graying, observed in light- and dark-haired individuals, is reversible within 6 months of cobalamin therapy.

A blunted masklike facies is extremely common in folate deficiency. Alternatively, there may be evidence of classic hyperthyroid or hypothyroid facies (associated with pernicious anemia). Special attention should be given to the eyes and eyebrows for signs of thyroid dysfunction.

Examination of the mouth may reveal glossitis with a smooth (depapillated), beefy red tongue with occasional ulceration of the lateral surface or gingival hyperplasia (antiepileptics). The neck may reveal thyromegaly (diffuse or with nodules) if there is associated disease. Increased jugular venous distention should alert the examiner to cardiovascular failure, with its attendant gallop, cardiomegaly (with or without pericardial effusions), pulmonary basal crepitations, pleural effusion, tender hepatomegaly, and pedal edema. Nontender hepatomegaly, but more often mild splenomegaly, may rarely be caused by extramedullary hematopoiesis in severe anemia, but a midepigastrium mass raises the ominous possibility of gastric carcinoma, which is three times as likely in patients with pernicious anemia.

An inverse correlation has been identified between the extent of anemia and neurologic dysfunction. Patients with normal complete blood count values often have neurologic signs and symptoms. In prolonged cobalamin deficiency, the neurologic examination reveals clear-cut evidence of involvement of posterior and pyramidal, spinocerebellar, and spinothalamic tracts. Among the earliest signs of posterior column dysfunction are loss of position sense in the index toes (before great toe involvement), which is elicited by passive movement, and loss of the ability to discern vibration of a high-pitched (256 cycles/sec) tuning fork. This is a very early elicitable, objective sign, which invariably precedes by many months the loss of ability to sense the vibration of a lower-pitched (128 cycles/sec) tuning fork. Usually the patient loses vibration sense to 256 cycles/sec from toe to hip before loss of 128 cycles/sec vibration sense even begins. Because of the slow coalescence of contiguous spinal cord lesions, a constellation of elicitable signs may be obtained. Upper motor neuron disease is indicated by weakness and progressive spasticity with increased muscle tone, exaggerated deep tendon reflexes with clonus, extensor plantar response, and incoordinate or scissor gait, which may progress to spastic paraplegia. The involvement of peripheral nerves may markedly modify these signs to include flaccidity and the absence of deep tendon reflexes. A positive Romberg sign is not uncommon, and a positive Lhermitte sign may be elicited. Loss of sphincter and bowel control, altered cranial nerve dysfunction with altered taste, smell, and visual acuity or color perception, and optic neuritis (unexplained predominance in males) may be other physical signs indicating cobalamin deficiency. Inability to carry out serial subtraction of 7 from 100 is a valuable test to document reduced cerebral function (the electroencephalogram often reveals slow wave frequency) in pernicious anemia.

Diagnostic Issues: Information From the Peripheral Smear and Bone Marrow Aspirate

Although not specific for megaloblastic anemia, macro-ovalocytes are the hallmark of megaloblastosis (see Fig. 37-7). However, only one-half with MCV values greater than 105 fl may have vitamin deficiency. In almost one-half of all cases, macrocytosis per se is not associated with megaloblastosis, and additional tests are necessary for complete diagnosis.

The frequency of hypersegmented PMNs (5% with five lobes or 1% with six-lobed PMNs) in patients with megaloblastic hematopoiesis is 98%. The sensitivity decreases to 78% in alcoholics, although the specificity of this finding is approximately 95%. With a combination of hypersegmented PMNs and macro-ovalocytosis, the specificity is 96% to 98%, and the positive predictive value of folate or cobalamin deficiency is about 94%.[9] Hypersegmentation of PMNs is insufficiently sensitive, when compared with metabolite levels, to be used as a clinical tool in the diagnosis of mild cobalamin deficiency[9] (see box on Diagnostic Bone Marrow Aspiration).

Masked Megaloblastosis

The term *masked megaloblastosis* is reserved for conditions in which true cobalamin or folate deficiency with anemia is not accompanied

Diagnostic Bone Marrow Aspiration

Is bone marrow aspiration always necessary to diagnose cobalamin- or folate-deficient megaloblastosis? With the addition of highly sensitive serum tests for the specific diagnosis of cobalamin and folate deficiency, the need for a bone marrow test is often dictated by the urgency to diagnose megaloblastosis (with results available in an hour). For example, in the case of florid hematologic disease with or without neurologic disease suggestive of cobalamin or folate deficiency, bone marrow aspiration carried out as soon as possible is invaluable in assisting the rapid diagnosis of megaloblastosis. However, in the outpatient setting, when the patient has a characteristic peripheral smear, or for a patient with a primary neuropsychiatric presentation, a case can be made to initiate the sequence of diagnostic tests without bone marrow aspiration by proceeding with measurement of serum levels of vitamins or metabolites (see Table 37-1). In a pregnant patient with pancytopenia with macro-ovalocytes, hypersegmented PMNs, and reticulocytopenia with a history of noncompliance with prenatal supplements (and no neurologic findings suggestive of cobalamin deficiency), bone marrow aspiration may not be necessary to initiate therapy for a strong presumptive diagnosis of folate deficiency. If there is no evidence of response within 10 days, bone marrow aspiration is indicated.

by classic findings of megaloblastosis in the peripheral blood and bone marrow. This occurs when there is a coexisting condition that neutralizes the tendency to generate megaloblastic cells (usually involving reduction in RBC hemoglobinization, as in iron deficiency or thalassemia).[9] A wide RBC distribution width (RDW) on the Coulter counter readout in the presence of a "normal" mean corpuscular hemoglobin or MCV may reflect megaloblastic anemia[9] or dimorphic anemia (macro-ovalocytes plus microcytic hypochromic RBCs). Because megaloblastic white blood cells and precursors are unaffected by deficient hemoglobinization, these pathognomonic findings (giant myelocytes and metamyelocytes, and hypersegmented PMNs) remain; the latter may persist for up to 2 weeks after replacement with cobalamin or folate.[8] The recognition of masked megaloblastosis should initiate investigations to rule out iron deficiency, anemia of chronic disease, or hemoglobinopathies. Appropriate replacement with cobalamin or folate elicits a maximal therapeutic benefit only when iron deficiency is corrected. Conversely, if combined iron and cobalamin deficiency (total gastrectomy or pernicious anemia) or iron and folate deficiency (pregnancy) is treated with iron alone, megaloblastosis will be unmasked.

APPROACH TO DIAGNOSIS AND THERAPY OF MEGALOBLASTOSIS

In general there are three stages in approaching a patient: *recognizing* that megaloblastic anemia is present; *distinguishing* whether folate, cobalamin, or combined folate and cobalamin deficiencies have led to the anemia; and diagnosing the *underlying disease* and *mechanism* causing the deficiency. Establishing that the patient does have megaloblastosis is, in theory, straightforward. This is easily done by first evaluating the complete blood count, the MCV, and the peripheral smear, followed by a bone marrow aspiration. Clues to whether cobalamin or folate deficiency is responsible for megaloblastosis can be obtained by serum cobalamin and serum folate levels; if these levels are borderline, additional testing of serum MMA and serum homocysteine can define the true nature of the deficiency.[9,175] However, this ideal and orderly workup is not always feasible in clinical practice, because the patient may present for the first time with megaloblastosis with or without associated neurologic disease; may be referred after a variable workup has already been initiated for possible megaloblastosis; may present with symptoms primarily attributed to a disease predisposing to cobalamin or folate deficiency; may present with a disease associated with hyperhomocysteinemia (discussed later), in which case anemia or neurologic dysfunction may only be a minor symptom; may present with isolated neurologic disease in the absence of anemia; or may be referred after empirical therapy has been given for presumed cobalamin or folate deficiency. The immediate question therefore pertains to the overall status of the patient.

If the patient is decompensated or decompensation is imminent, obtain serum folate and cobalamin levels and bone marrow aspiration to confirm megaloblastosis and proceed with transfusion of 1 unit of packed RBCs *slowly,* with vigorous diuretic therapy to obviate further congestive heart failure from fluid overload; this mandates close monitoring and correction of fluid and electrolyte imbalance. Cobalamin and folate should be administered simultaneously in full doses. Transfusion does not alter serum folate or cobalamin levels.

If the patient is moderately symptomatic (but not in heart failure), the strong likelihood of a dramatic response (in the sense of well-being and relief of sore tongue) within 2 to 3 days even before hematologic improvement argues against immediate blood transfusion.[9] Therefore (and provided the patient is unlikely to decompensate in the short-term) proceed with appropriate diagnostic workup as for the well-compensated patient.

If the patient is well compensated and in the outpatient setting, the physician has time to develop an orderly sequence of diagnostic tests. First, check the peripheral smear and rule out other macrocytic anemias (thin macrocytes with a normoblastic marrow in contrast to macro-ovalocytes) (see Fig. 37-7). Draw blood for cobalamin and folate levels (*before* the patient's first hospital meal) to sort out whether the problem is caused by a deficiency of folate or cobalamin, or both, or some other deficiency (see Table 37-1). Assuming that there is no urgency to make the diagnosis, the physician can elect to wait for the results of these tests before proceeding with the next test in the diagnostic workup. If making the diagnosis is urgent, a cost-effective test is the bone marrow aspirate; results indicating megaloblastosis (or not) can be available within an hour. If bone marrow aspiration is performed, samples are sent for special stains and flow cytometry (megaloblastic erythropoiesis can resemble erythroleukemia) and cytogenetic analysis (myelodysplastic syndromes can exhibit some megaloblastic changes in the erythroid series, but megaloblastic granulopoiesis is not seen). If the marrow is not obviously megaloblastic but the iron stain reveals absent stores, review the morphologic evaluation again with special emphasis on granulocytic precursors and promegaloblasts, and look for more subtle megaloblastic changes.

If the patient refuses bone marrow aspiration and serum cobalamin and folate levels are equivocal (i.e., in the low-normal range), a strong case can be made to test for serum homocysteine and MMA. Serum MMA and homocysteine levels are ordered together (the same sample remaining from the serum sent for cobalamin and folate levels may be used if it was frozen). Integrating the results for serum MMA and homocysteine levels (which will be available after a week or more) with those for serum cobalamin and folate levels can help distinguish cobalamin and folate deficiencies (see Table 37-1). A normal MMA and homocysteine level eliminates cobalamin deficiency with 100% confidence, and normal homocysteine levels suggest that megaloblastic anemia is not caused by folate deficiency. These tests are particularly useful if the patient has pure neurologic disease or if there are associated conditions such as iron deficiency or thalassemia that can mask megaloblastosis. Administration of folate or cobalamin will reduce elevated serum homocysteine and MMA levels to basal values by 1 week, so there is only a narrow window to clinch the diagnosis using metabolite tests.[9] In the rare situation when a defect in cobalamin or folate metabolism is suspected, early consultation with experts who have published in this area is advised.[108,118]

A reticulocyte count is useful to follow the patient's response to appropriate replacement therapy. Additional supporting studies to document increased serum LDH, haptoglobin, and bilirubin (evidence for intramedullary hemolysis) may be performed.

When the megaloblastic state is established, try to determine the underlying mechanism of cobalamin or folate deficiency. The cause of folate deficiency is usually sorted out by this time from the history,

Practicing Classical Medicine Without the (Classical) Schilling Test

The Schilling test was used to identify the locus of cobalamin malabsorption and, in some instances such as pernicious anemia or bacterial overgrowth, the cause of cobalamin deficiency. However, this test has been unavailable since 2003 in the United States. Because only 50% of patients with pernicious anemia have serum anti–intrinsic factor (IF) antibodies, there are limitations in differentiating the other one-half without measurable anti-IF antibodies from those with food-bound cobalamin malabsorption and others with an intestinal cause for cobalamin malabsorption. A minimalist approach is to work around the nonavailability of the Schilling test and use a classical clinical approach to rule out potential differential diagnoses of cobalamin deficiency (see box on Etiopathophysiologic Classification of Cobalamin Deficiency). For example, most conditions predisposing to cobalamin deficiency should be clinically manifest by the time cobalamin deficiency is evident. It should therefore be possible to identify several conditions through a detailed dietary history or past medical history, travel history, and drug history to suggest a dietary cause, esophagogastroduodenal disease, pancreatic insufficiency, impaired bowel motility, or other autoimmune diseases. The history and physical examination could provide further leads and suggest additional focused laboratory testing for rare conditions (stool for ova, anti–tissue transglutaminase antibodies, lipase, gastrin, intestinal biopsy, or radiographic contrast studies for stasis, strictures, fistulas). With no further leads, and therefore by default, one can assume that the diagnosis is either pernicious anemia or food-cobalamin malabsorption, which are both treated with similar replacement doses of cobalamin. For the younger patient with megaloblastic anemia, differentiating juvenile pernicious anemia and congenital IF deficiency would warrant measurement of gastric juice for IF and achlorhydria, deoxyribonucleic acid (DNA) for gastric IF can identify hereditary megaloblastic anemia, and DNA for mutations in cubam receptor (amnionless/cubulin genes) could identify Imerslund-Gräsbeck syndrome.

Thus the history, physical findings, and focused laboratory tests with careful clinical follow-up can potentially identify the cause of the majority of cases of cobalamin deficiency and bypass the need for a Schilling test.

physical examination, and the clinical setting. If pure folate deficiency has been prolonged, expect associated cobalamin deficiency to ensue (special emphasis should be given to identifying subtle manifestations of neurologic disease). If cobalamin deficiency is suspected, test for serum anti-IF antibodies (highly specific for pernicious anemia).

See box on Practicing Classical Medicine Without the (Classical) Schilling Test.

THERAPY

Routinely, treatment with full doses of parenteral cobalamin (1 mg/day) and oral folate (folic acid) (1 to 5 mg) before knowledge of the type of vitamin deficiency is established should be reserved for the severely ill patient. An appropriate regimen for conditions in which cobalamin replenishment can correct cellular cobalamin deficiency (but not correct the underlying problem that led to the deficiency, such as pernicious anemia) is 1 mg of intramuscular or subcutaneous cyanocobalamin per day (week 1), 1 mg twice weekly (week 2), 1 mg/week for 4 weeks, and then 1 mg per month for life (about 15%, or 150 mcg, is retained 48 hours after each 1-mg cobalamin injection). *Ideally, this protocol for rapid correction of cobalamin deficiency and complete replenishment of cobalamin stores should be used in the beginning for all patients with cobalamin deficiency, regardless of the etiology* (see box on Modified Therapeutic Trials).

Parenteral hydroxocobalamin should be reserved for all inborn errors of cobalamin metabolism. There is no major advantage of other preparations over generic cyanocobalamin. There is equivalence between oral 2-mg cobalamin tablets consumed daily (where cobalamin is passively absorbed at high doses) and traditional monthly parenteral treatment with 1 mg of intramuscular/subcutaneous cobalamin among those requiring long-term cobalamin. So for patients who refuse monthly parenteral therapy, or prefer daily oral therapy, or in those with disorders of hemostasis, cobalamin (1 to 2 mg/day as tablets) can be recommended for all those patients with cobalamin malabsorption.[8,9] The physician must ensure that the patient is compliant and demonstrates adequate cobalamin levels as well as resolution of hematologic and neurologic abnormalities on follow-up. For nutritional cobalamin deficiency (e.g., vegetarians) when the entire circuitry in cobalamin absorption is intact, daily oral cobalamin of 5 to 10 mcg (found in conventional multivitamin tablets in the United States) taken for a lifetime of vegetarianism will suffice. However, if malabsorption of food-bound cobalamin is suspected (especially in the elderly with achlorhydria), higher doses of daily oral cobalamin (equal to or greater than 1000 mcg/day) is required.[176]

The bioavailability of oral cobalamin can be reduced by about 40% when it is taken with a meal; so taking cobalamin on an empty stomach will lower losses in the stool. More than 98% of all the cobalamin in feces is in the form of cobalamin analogues, and about 80% of the ingested cobalamin is converted to analogues by microorganisms in the gut.[177]

Oral folate (folic acid) at doses of 1 to 5 mg/day results in adequate absorption (even where intestinal malabsorption of physiologic food folate is present). Therapy should be continued until complete hematologic recovery is documented. If the underlying cause leading to folate deficiency is not corrected, folate may be continued. Folinic acid (i.e., 5-formyl-THF [leucovorin]) should be reserved *only* for rescue protocols involving antifolates (methotrexate or trimethoprim-sulfamethoxazole), for 5-fluorouracil modulation protocols, after nitrous oxide toxicity, or in pediatric cases involving cerebral folate deficiency or inborn errors of folate metabolism. It is too expensive for conventional repletion in folate-deficient states in adults.

Response to Replenishment

The response of the patient to appropriate replacement is reversion of megaloblastic hematopoiesis to normal hematopoiesis within the first 12 hours; by 48 hours normal hematopoiesis is reestablished, and the only evidence for a prior megaloblastic state may be the persistence of a few giant metamyelocytes. Because megaloblastosis caused by cobalamin or folate deficiency can be reversed in 24 hours by administration of folate (i.e., a nutritious hospital meal), delay of a diagnostic bone marrow aspirate should be avoided. Clinically the first 36 to 48 hours are often highlighted by the awakening of an occasional semistuporous individual whose "chief complaint" is amazement at the remarkably improved sense of well-being experienced, with increased alertness and appetite and reduced soreness of the tongue. The elevated serum MMA and homocysteine levels will return to normal by the end of the first week.

Accelerated turnover of normal DNA in erythroid precursors is associated with an increase in serum urate level, which usually peaks by the fourth day, and with increased cellular phosphate uptake for nucleotide synthesis. This may precipitate an attack of gout if the patient has a "gouty predisposition." The reticulocyte count increases by the second to third day and peaks by the fifth to eighth day (the peak reticulocyte count is directly proportional to the degree of preexisting anemia). This is followed by a rise in RBC count, hemoglobin, and hematocrit by the end of the first week, which normalizes in approximately 2 months, regardless of the initial degree of anemia. By the end of the third week, the RBC count should be above 3×10^6/mm^3; if it is not, additional causes of underlying iron deficiency, hemoglobinopathy, chronic disease, or hypothyroidism should be considered (Table 37-6).

Table 37-6 Causes of Megaloblastosis Not Responding to Therapy With Cobalamin or Folate

WRONG DIAGNOSIS
Combined folate and cobalamin deficiencies being treated with only one vitamin
Associated iron deficiency
Associated hemoglobinopathy (e.g., sickle cell disease, thalassemia)
Associated anemia of chronic disease
Associated hypothyroidism

Hypersegmented PMNs continue to remain in the blood for 10 to 14 days; however, the number of normal PMNs and platelets rises and normalizes within the first week. During this process, there may be a transient left shift to include myeloid precursors. The reduced intramedullary hemolysis (as a result of normalized hematopoiesis) leads to a gradual reduction in the serum bilirubin level by the end of the first week, and LDH levels will drop concomitantly.

In response to cobalamin, progression of neurologic damage and dysfunction is inhibited. In general the degree of functional recovery is inversely related to the extent of disease and duration of signs and symptoms. As a rough estimate, signs and symptoms that have been present for less than 3 months are usually completely reversible; with longer duration, there is invariable residual neurologic dysfunction. The reversibility of neurologic damage is slow (a maximal response may take 6 months). Substantial increments (in recovery) are unlikely to be gained after the first 12 months of appropriate therapy. However, most neurologic abnormalities have improved in up to 90% of patients with documented subacute combined degeneration.

Follow-Up

Patients with neurologic dysfunction from cobalamin deficiency have traditionally been given more frequent doses of cobalamin (biweekly rather than monthly therapy for the first 6 months), despite the lack of evidence that this form of therapy is more beneficial. This approach nevertheless serves a purpose in that improvement in neurologic status can be carefully documented. Once maximal responses have been established, most patients can be treated with life-long cobalamin with a dose that is appropriate for the underlying cause of cobalamin deficiency. Follow-up outpatient visits every 6 months should be instituted to ensure adequate maintenance of hematopoiesis, as well as early diagnosis of other diseases commonly associated with the cobalamin- or folate-deficient state. Follow-up of patients with pernicious anemia suggest that individuals older than 60 years are prone to developing iron deficiency that arises from poor iron absorption from achlorhydria.[9] All patients with pernicious anemia should be screened for iron deficiency at the beginning and during follow-up.

Patients with pernicious anemia have a twofold increase in proximal femur and vertebral fractures and a threefold increase in distal forearm fractures. Finally, three studies (from Sweden, the United States, and Denmark) on a total of nearly 15,000 patients with pernicious anemia have identified an excess risk for gastric cancers within the first few years of diagnosis[178]; so it is prudent to recommend upper endoscopy for these patients.

ROUTINE SUPPLEMENTATION OF COBALAMIN AND FOLATE

Routine periconceptional supplementation of folate for normal women[9] and in 10 times higher doses for women at risk for delivery of subsequent babies with NTDs[9] provides effective prophylaxis against the development of NTDs (Table 37-7). Food fortification with folic acid (140 mcg/100 g flour) has nearly eliminated folate deficiency[179,180]—the prevalence of low serum folate level decreased from 18.4% to 0.8% with a small (0.3 g/dL) increase in hemoglobin (for men an increase from 15.1 to 15.4 g/dL and for women from 13.3 to 13.6 g/dL)[181]; it has consistently reduced NTDs[143,182]; and it is a cost-effective intervention.[183] Food fortification was intended to provide only one-quarter of the recommended dietary allowance of folate. A very brief focused interaction involving physician advice combined with a booster phone call and starter bottle of folic acid tablets can markedly increase a woman's regular intake of folic acid (increase by 68% versus 20% in the control group).[184] Distressingly, however, two decades after the landmark studies showed the way to prevention of first occurrence of NTDs, women in large areas of North India continue to subsist on monotonous and largely vegetarian diets containing only one-third to one-fifth of the RDA of folate required,[25,44] which can well explain the shockingly high incidence of NTDs.[134] Folic acid supplements during early pregnancy appear to reduce the risk for isolated cleft lip (with or without cleft palate) by about one-third.[185]

Table 37-7 Indications for Prophylaxis With Cobalamin or Folate

PROPHYLAXIS WITH COBALAMIN
Infants on specialized diets*
Premature infants
Infants of mothers with pernicious anemia*
Infants and children of mothers with nutritional cobalamin deficiency
Vegetarianism and poverty-imposed near-vegetarianism*
Total gastrectomy†
PROPHYLAXIS WITH FOLIC ACID‡
All women contemplating pregnancy (at least 400 mcg/day)§
Pregnancy and lactation, premature infants
Mothers at risk for delivery of infants with neural tube defects‖¶
Hemolytic anemias/hyperproliferative hematologic states
Patients with rheumatoid arthritis or psoriasis on therapy with methotrexate#
Patients on antiepileptic drugs
Patients with ulcerative colitis

*For vegetarians, prophylaxis with cobalamin (5- to 10-mcg tablet/day) orally should suffice. In all other conditions involving any abnormality of cobalamin absorption, cobalamin tablets of 1000 mcg/day should be administered orally to ensure that cobalamin transport by passive diffusion across the intestine is sufficient to meet daily needs.
†Consider late development of cobalamin deficiency and iron malabsorption (prophylaxis with oral cobalamin and iron).
‡Ensure that the patient does not have a cobalamin deficiency before initiating long-term folate prophylaxis.
§For prevention of first occurrence of neural tube defects.
‖Previous delivery of a child with neural tube defects (e.g., anencephaly, spina bifida, meningocele) imparts a 10-fold greater risk for subsequent delivery of infant with neural tube defects.
¶Folic acid (4 mg/day) administered periconceptionally and throughout the first trimester.
#To reduce toxicity of the antifolate.

The administration of folate and cobalamin in addition to the standard administration of intramuscular iron to premature infants less than 36 weeks of gestation significantly improved hemoglobin values.[186] For the anemia of prematurity, addition of cobalamin and folate to erythropoietin and orally and intravenously administered iron appeared more effective in stimulating erythropoiesis among premature infants, when compared with erythropoietin, iron, and low-dose folate alone[187]; so this should be the standard of care.

Supplementation with folate during pregnancy also helps to prevent premature delivery of low-birth-weight infants,[8] and routine supplementation for premature infants and lactating mothers is also recommended.

In addition to hematologic diseases leading to increased folate requirements (e.g., autoimmune hemolytic anemia, β-thalassemia), folic acid supplements reduce the hepatotoxicity and gastrointestinal intolerance of methotrexate in psoriasis[9,188] and rheumatoid arthritis[189] without impairing the efficacy of methotrexate.

Supplementation with folic acid protects against the development of colorectal neoplasia in high-risk patients with ulcerative colitis.[9]

A recent innovative large-scale universal program to harness more efficient ways to use existing public health structures has been described. This program, which involved weekly iron–folic acid supplementation combined with a regular deworming program, was able to successfully improve the hemoglobin and iron status among 52,000 Vietnamese women of reproductive age.[190] Similar approaches are applicable for thousands of women of reproductive age in Southeast Asia and Africa. Anemia with a hemoglobin value of less than 11 g/dL is found in 75% of children[191]; although this is primarily related to low iron stores, there is also an association with low folate stores. There would be additional benefit of cobalamin supplements for women who are already at risk for cobalamin deficiency because of poverty-imposed near-vegetarianism or for those who are vegetarians. For schoolchildren, simple community-level interventions, such as micronutrient fortification (using a premix added to school lunch meals), that build upon the infrastructure of an existing program have proven to be contextually acceptable and efficacious in improving folate and cobalamin (in addition to vitamin A and iron) status in Himalayan villages of India.[192] Such programs are critically important to the health of both women and their children (discussed later). Table 37-7 summarizes conditions that warrant routine folate or cobalamin supplementation.

Studies have shown that iron plus folic acid supplementation was beneficial to young children in a low-income area in Nepal where there was no malaria risk but iron deficiency was common[193]; therefore in this setting, routine iron plus folic acid supplementation is likely to have long-term benefits on several areas of physical growth and development, including cognitive performance. However, in areas where malaria is very common, widespread control of iron (and folate) deficiency anemia among children should be accompanied by intermittent preventive malaria therapy.[194,195] This is relevant to very young children in Africa who invariably have a multifactorial basis for severe anemia (hemoglobin less than 5 g/dL)—which includes malaria, bacteremia, hookworm, human immunodeficiency virus (HIV), glucose-6-phosphate dehydrogenase deficiency, and vitamin A, as well as 30% who have cobalamin deficiency.[196] There was an apparently lower incidence of folate deficiency in this cohort; however, because of cobalamin deficiency–associated methyl-folate trapping and the associated malaria-induced hemolysis in these children, there could well have been an artificial increase in serum folate. This is because red cells contain 30 times more folate than that which is found in the serum. Therefore the serum folate level may be falsely elevated, leading to an underestimation of the extent of folate deficiency. Of course the use of metabolite assays would have doubtless increased the prevalence of both cobalamin and folate deficiency in these populations.[7,75,197] However, this is impractical in resource-poor areas, so the prudent approach is to assume that these children also have folate deficiency and treat them with full replacement doses of cobalamin and folate. Only with correction of underlying deficiency of iron, cobalamin, and folate deficiency, together with other causes for anemia, will normal hematopoiesis be initiated.

Following food fortification, the total folate intake of most U.S. children 1 to 13 years of age does meet the estimated average requirement,[198] but children given supplements are at risk for exceeding the tolerable upper intake level; this remains a concern because the long-term effects are unknown. Whereas folic acid supplements consumed in excess of 1 mg/day can mask hematologic symptoms of cobalamin deficiency, it has been found that 94% of U.S. adults who do not consume supplements, or who consume less than 400 mcg of folic acid per day from supplements, do not exceed the upper limit in intake for folic acid.[199] There is also no evidence that taking high-folate supplements or consuming large amounts of folate-fortified foods places individuals at risk for exacerbating any underlying cobalamin deficiency.[200]

Is there a role for cobalamin fortification of foods? A strong case can to be made to consider the fortification of flour (or other contextually relevant food vehicle in developing countries) with small amounts of cobalamin to serve the majority of the population whose dietary intake of animal-source foods is poor. However, this type of fortified food will not benefit those (in developed countries) with food-cobalamin malabsorption; these individuals usually need the equivalent of 1 mg of oral cobalamin daily, an amount that could not possibly be achieved by the small amount of cobalamin added to fortify foods. Other issues related to cobalamin analogue formation upon exposure to light or mixing with other food ingredients and other stability issues during storage have not been resolved; hence this topic remains a work in progress.

HYPERHOMOCYSTEINEMIA

Normally homocysteine is metabolized by the methylation reaction (discussed earlier) and by a second trans-sulfuration pathway, which essentially eliminates homocysteine as a potential source of methionine. In the trans-sulfuration pathway, cystathionine β-synthase catalyzes the condensation of homocysteine with serine in the presence of pyridoxyl phosphate (vitamin B_6) to form cystathionine, which is further cleaved by a vitamin B_6–dependent γ-cystathionase to form cysteine and α-ketobutyrate. The cysteine that is formed can be used for synthesis of the antioxidant glutathione, a key component that defends against oxidative stress within cells. In some tissues like liver, homocysteine can also be remethylated to methionine by the transfer of a one-carbon moiety from betaine by the enzyme, homocysteine methyltransferase, which is restricted to the liver and kidney. Thus the level of plasma homocysteine depends on genetically regulated levels of essential enzymes in one-carbon metabolism, the intake of folic acid or food folates, vitamin B_6, cobalamin, and other acquired conditions (dehydration, renal dysfunction, antifolates, and nitrous oxide).

Chronic hyperhomocysteinemia is established as a major risk factor in occlusive vascular diseases.[41] These include myocardial infarctions from coronary atherosclerosis, extracranial carotid artery stenosis, vascular disease in end-stage renal failure, thromboangiitis obliterans, aortic atherosclerosis, venous thromboembolism, placental abruption or infarction, and recurrent stillbirths. Hyperhomocysteinemia is also associated with reduced bone mineral density and increased incidence of fractures,[201] increased small-vessel cerebrovascular disease–related strokes,[202,203] dementia and Alzheimer disease.[204]

There is more than one mechanism for transport of homocysteine across the microvillous membrane of the human placenta.[205] Raised maternal plasma levels of homocysteine primarily from cobalamin and folate deficiency are associated with various pregnancy complications. These include preeclampsia and spontaneous pregnancy loss,[172,206-209] placental abruption,[206,208,210] recurrent pregnancy loss,[206,208,211] fetal growth restriction[207,208] preterm birth,[212] and stillbirth.[207] The adverse outcomes for the baby include NTDs and congenital malformations.[207,208] Normalization of maternal homocysteine level with cobalamin and folate and improvement of these pregnancy outcomes for some complications[208,211] indicate that some of these risks can be reduced with good nutrition.

Homocysteine-Lowering Trials and Primary Versus Secondary Prevention

Most homocysteine-lowering intervention trials have been underpowered; they have looked at populations in which the serum homocysteine level has been borderline elevated rather than being elevated to the higher level (over 20 μM); and they have only had a follow-up of less than 5 years. Moreover, many of the intervention trials have been compromised by the advent of food fortification with folate or by enrolled patients who were consuming multivitamins containing folic acid. A recent review of this "homocysteine controversy"[213] has noted that the duration of follow-up in most studies has been too short (and likely dictated by the dramatic results from the use of antihypertensives and statins, which required only short follow-up to demonstrate positive effects). The point made is that such expectations are unrealistic for atherosclerosis because the atherosclerotic

plaque commonly takes 30 to 40 years to develop into a full-blown clinical event. Moreover, there is a distinct difference between primary prevention of the earliest stages of a disease process and attempts to intervene after demonstrated vascular damage (secondary prevention). (Indeed, it was only longer follow-up for 10 to 15 years that established the primacy of blood glucose control in management of patients with diabetes).

Despite the failure of homocysteine-lowering therapy in several trials related to secondary prevention of atherosclerotic disease, this has not eliminated the possibility of a beneficial role of lowering homocysteine in primary prevention of diseases. Indeed, clinical trials that used folates have suggested that folate also has a role in reduction in strokes,[139] reduction in the rate of cognitive decline among healthy older adults,[140] and a reduction in age-related (sensorineural) hearing loss.[141] There is also grade A evidence from randomized controlled trials for a role of folate in combination with cobalamin for reduction of hip fractures,[136] subclinical atherosclerosis,[137] and stroke prevention.[139] In addition, the value of a triple combination of folate, pyridoxine, and cobalamin to reduce age-related macular degeneration in women is also established[138] (see Table 37-4).

By inference, in addition to clinical presentation with nutritional anemia, patients can also present with any of these additional clinical conditions, as well as a variety of pregnancy complications with or without poor pregnancy outcomes (affecting the newborn), when they have long-standing untreated hyperhomocysteinemia.

Homocysteine and Mild Cognitive Impairment

All inherited diseases involving a severe elevation of homocysteine are associated with cognitive deficit and poorer neurocognitive performance. Accelerated brain atrophy is often a characteristic among those with mild cognitive impairment who then go on to develop Alzheimer disease. Now a randomized controlled trial from the UK—where folate fortification of food is not mandatory—among elderly patients with mild cognitive impairment has identified that lowering of homocysteine level by B vitamins over 2 years did slow the rate of brain atrophy by almost 30%.[73] This is consistent with another randomized controlled trial (in a region without folate fortification of food) that demonstrated beneficial effects of folates on cognition over 3 years.[140] While awaiting larger confirmatory trials, these studies suggest that homocysteine-lowering therapy can slow down the accelerated rate of brain atrophy that is found with mild cognitive impairment.

Homocysteine Lowering and the Progression of Diabetic Nephropathy

Even though patients with diabetic nephropathy have elevated levels of homocysteine, attempts to use a combination of high doses of oral B vitamins (folic acid, pyridoxine, cobalamin) to reduce homocysteine concentrations have now been shown to *worsen* their kidney disease and place them at greater risk for dying from serious vascular events.[214] Hence there is *no* justification for using high-dose B vitamins in this setting or outside the framework of properly conducted clinical research.

FOLATE FORTIFICATION OF FOOD AND THE RISK FOR CANCER

Three large prospective studies[215-217] suggest that long term folate intake actually *decreases the risk* for initiation or early development of colorectal cancer[217]; in addition, there appears to be a diminished to nonexistent influence on (precancerous) adenomas. Collectively, these papers provide reassurance that the fortification of food to prevent NTDs in women of childbearing age has not led to harm among the remaining "nontargeted" population of adults. There also could be long-term benefits in primary prevention (see Table 37-4).

FUTURE DIRECTIONS

In this age of spiraling costs for health care delivery, and the ongoing debate on ways to reduce these costs, few instances in internal medicine and hematology yield more satisfying dividends than diagnosing and treating cobalamin and folate deficiency using generic vitamins that are "dirt-cheap"—costing only one or two cents a day. These conditions are devastating when undiagnosed or misdiagnosed or when cobalamin deficiency is treated with folate alone. Recognition of various populations at risk and the clinical scenarios in which folate and cobalamin deficiency are likely to be present, and the availability of sensitive and specific tests, should reduce uncertainty in diagnosis. The studies on folate supplementation during pregnancy that identified new folate-responsive NTDs and neurocristopathies are a paradigm for identification of hitherto unrecognized roles for other nutrients in human development. The significant impact of supplemental folates in relieving human suffering consonant with reducing costs for intensive and long-term care of infants with prematurity or NTDs is a major achievement and outstanding example of cost-effective preventive medicine. Other recent advances from randomized controlled studies indicate beneficial effects of supplemental folate and cobalamin in the prevention of diverse diseases. The newest information related to the influence of folates and cobalamin during development in utero—especially on behavioral neuroscience—allows us to peer into a new field where groundbreaking discoveries will be made in the coming decade. Finally in early 2012, we identified a molecular link between folate deficiency and Human Papillomavirus (type 16)-induced cancer.[218] Because this virus is the most common cause of cervical cancer worldwide (and also responsible for a significant number of vulvar, vaginal, penile, anal, and oropharyngeal cancers), such studies open the door to new investigations into the potential role of these vitamins in the field of preventive oncology.

CHAPTER 38

THALASSEMIA SYNDROMES

Patricia J. Giardina and Stefano Rivella

The thalassemia syndromes are a heterogeneous group of inherited anemias characterized by defects in the synthesis of one or more of the globin chain subunits of the hemoglobin tetramer. The clinical syndromes associated with thalassemia arise from the combined consequences of inadequate hemoglobin production and imbalanced accumulation of globin subunits. The former causes hypochromia and microcytosis; the latter leads to ineffective erythropoiesis (IE) and hemolytic anemia. Clinical manifestations are diverse, ranging from asymptomatic hypochromia and microcytosis to profound anemia, which can be fatal in utero or in early childhood if untreated. This heterogeneity arises from the variable severities of the primary biosynthetic defects and coinherited modifying factors, such as increased synthesis of fetal globin subunits or diminished or increased synthesis of α-globin subunits. Palliative treatment of the severe forms by blood transfusion is eventually compromised by the concomitant problems of iron overload, alloimmunization, and bloodborne infections.

As a group, the thalassemias represent the most common single genetic disorder known. In many parts of the world, they constitute major public health problems. Laboratory analysis of these disorders has been one of the most productive and enlightening endeavors of biomedical research. Study of the molecular defects underlying the thalassemia syndromes has led to fundamental advances in our understanding of eukaryotic gene structure and function. For each of these reasons, a thorough understanding of thalassemia and its related disorders is essential to hematologists. This chapter reviews the major features of these syndromes. Readers wanting more detailed information than can be included here are referred to more comprehensive monographs elsewhere.[1,2]

The classification, genetic basis, and pathophysiology of the thalassemia syndromes are based on a thorough understanding of the human hemoglobins, their biosynthesis, their encoding globin gene families, and their roles as soluble oxygen-carrying molecules. Therefore, readers of this chapter should first familiarize themselves with the material presented in Chapter 31. The material presented in this chapter is also substantially clarified by prior reading of Chapters 33 and 34 because the principles underlying the pathophysiology of and therapy for thalassemia draw heavily on knowledge of iron metabolism.

DEFINITIONS AND NOMENCLATURE

The term *thalassemia* is derived from a Greek term that roughly means "the sea" (Mediterranean) in the blood.[1] It was first applied to the anemias frequently encountered in people from the Italian and Greek coasts and nearby islands.[3-5] The term is now used to refer to inherited defects in globin-chain biosynthesis. Individual syndromes are named according to the globin chain whose synthesis is adversely affected. Thus, α-globin chains are absent or reduced in patients with α-thalassemia, β-globin chains in patients with β-thalassemia, δ-globin and β-globin chains in patients δβ-thalassemia, and so forth. In some contexts, it is also useful to subclassify the syndromes according to whether synthesis of the affected globin chain is totally absent (e.g., β^0-thalassemia) or only partially reduced (e.g., β^+-thalassemia).

The most common forms of thalassemia arise from total absence of structurally normal globin chains or a partial reduction in their synthesis. In contrast to the "structural" hemoglobinopathies (e.g., sickle cell anemia), which are characterized by the production of normal amounts of mutant globin chains having deranged physical or chemical properties, the thalassemias are quantitative disorders: the primary lesion lies in the amount of globin produced. However, some rare forms of thalassemia are characterized by the production of structurally abnormal globin chains in reduced amounts. These thalassemic hemoglobinopathies share features of thalassemia as well as those of structural hemoglobinopathies.[6]

Some mutations alter the patterns of fetal to adult hemoglobin switching. These conditions, called *hereditary persistence of fetal hemoglobin,* are not generally associated with clinical symptoms; nonetheless, they merit consideration in this chapter. Their importance lies in their role as modulating factors when coinherited with other hemoglobinopathies; in their usefulness as models for investigating the molecular basis for globin gene regulation during human development; and as paradigms for rational therapy for the major β-chain hemoglobinopathies, namely, sickle cell anemia and β-thalassemia.

ETIOLOGY, EPIDEMIOLOGY, AND PATHOPHYSIOLOGY

The thalassemias are inherited as pathologic alleles of one or more of the globin genes located on chromosomes 11 and 16 (see Chapter 31). These lesions range from total deletion or rearrangement of the loci to point mutations that impair transcription, processing, or translation of globin mRNA. The precise nature of the defects is summarized in a later section.

Thalassemias have been encountered in virtually every ethnic group and geographic location. They are most common in the Mediterranean basin and tropical or subtropical regions of Asia and Africa. The "thalassemia belt" extends along the shores of the Mediterranean and throughout the Arabian peninsula; Turkey; Iran; India; and southeastern Asia, especially Thailand, Cambodia, and southern China.[7-10] The prevalence of thalassemia in these regions is in the range of 2.5% to 15%. Similar to sickle cell anemia, thalassemia is most common in areas historically affected by endemic malaria. Malaria seems to have conferred selective survival advantage to thalassemia heterozygotes in which infection with the malarial parasite is believed to result in milder disease and less impact on reproductive fitness.[1,2,11] Therefore, the gene frequency for thalassemia has become fixed and high in populations exposed to malaria over many centuries.

PATHOPHYSIOLOGY: GENERAL PRINCIPLES

The pathophysiology and molecular genetics of individual forms of thalassemia are closely intertwined. Therefore, detailed consideration of these syndromes is best deferred to their individual subsections. This section considers only mechanisms common to the pathogenesis of all of these syndromes.[1-5,12]

The primary lesion in all forms of thalassemia is reduced or absent production of one or more globin chains. For all practical purposes, the major impact on clinical well-being occurs only when these

lesions affect the α- or β-globin chains necessary for the synthesis of hemoglobin (Hb A; $\alpha_2\beta_2$). (Severe impairment of γ-, ε-, or ζ-globin production is presumably lethal in utero.) One consequence of reduced globin-chain production is immediately apparent: reduced production of functioning hemoglobin tetramers. As a result, hypochromia and microcytosis are characteristic of virtually all patients with thalassemia. In the milder forms of the disease, this phenomenon may be barely detectable.

The second consequence of impaired globin biosynthesis is unbalanced synthesis of the individual α- and β-subunits. Hemoglobin tetramers are highly soluble and have reversible oxygen-carrying properties exquisitely adapted for oxygen transport and delivery under physiologic conditions. Free or "unpaired" α-, β-, and γ-globin chains are either highly insoluble or form homotetramers (Hb H and Hb Bart) that are incapable of releasing oxygen normally and are relatively unstable and precipitate as the cell ages. For poorly understood reasons, no compensatory regulatory mechanism exists whereby impaired synthesis of one globin subunit leads to a compensatory downward adjustment in the production of the other (partner) globin chain of the hemoglobin tetramer. Thus, whereas useless excess α-globin chains continue to accumulate and precipitate in β-thalassemia, excess β-globin chains form Hb H in α-thalassemia. During uterine development, excess γ-globin chains form Hb Bart in individuals with α-thalassemia.

The abnormal solubility or oxygen-carrying properties of these chains lead to a variety of physiologic derangements. Indeed, in the severe forms of thalassemia, it is the behavior of the unpaired globin chains accumulating in relative excess that dominates the pathophysiology of the syndrome rather than the mere underproduction of functioning hemoglobin tetramers. The precise complications of this pathophysiologic phenomenon are diverse and depend on the amount and the identity of the globin chain accumulating in excess. For the moment, the fundamental principle that must be appreciated is that thalassemias cause symptoms by underproduction of hemoglobin and by accumulation of unpaired globin subunits. The unpaired subunits are usually the major sources of morbidity and mortality.

The predominant circulating hemoglobin at the moment of birth is fetal hemoglobin (Hb $F^{\alpha_2\gamma_2}$) (see Chapter 31). Although the switch from γ- to β-globin biosynthesis begins before birth, the composition of hemoglobin in the peripheral blood changes much later because of the long life span of normal circulating red blood cells. Hb F is thus slowly replaced by adult hemoglobin (Hb A) so that infants do not depend heavily on normal amounts and function of Hb A until they are between 4 and 6 months old. The pathophysiologic consequences of these considerations are that whereas α-chain hemoglobinopathies tend to be symptomatic in utero and at birth, individuals with β-chain abnormalities are asymptomatic until 4 to 6 months of age. These differences in the onset of phenotypic expression arise because α-chains are needed to form Hb F and Hb A, but β-chains are required only for Hb A.

β-THALASSEMIA SYNDROMES

Nomenclature

Many different mutations cause β-thalassemia and its related disorders, such as δβ-thalassemia and the silent carrier state. They are inherited in a multitude of genetic combinations responsible for a heterogeneous group of clinical syndromes. β-Thalassemia major, also known as Cooley anemia or homozygous β-thalassemia, is a clinically severe disorder that results from the inheritance of two β-thalassemia alleles, one on each copy of chromosome 11. As a consequence of diminished Hb A synthesis, the circulating red blood cells (RBCs) are very hypochromic and abnormally shaped; they contain markedly reduced amounts of hemoglobin. Accumulation of free α-globin chains leads to the deposition of precipitated aggregates of these chains to the detriment of the erythrocyte and its precursor cells in the bone marrow (BM). The anemia of thalassemia major is so severe that long-term blood transfusions are usually required.

The term *β-thalassemia intermedia* is applied to a less severe clinical phenotype in which significant anemia occurs but chronic transfusion therapy is not absolutely required. It usually results from the inheritance of two β-thalassemia mutations, one mild and one severe; the inheritance of two mild mutations; or, occasionally, the inheritance of complex combinations, such as a single β-thalassemia defect and an excess of normal α-globin genes, or two β-thalassemia mutations coinherited with heterozygous α-thalassemia (in this last form, known as αβ-thalassemia, the α-thalassemia allele reduces the burden of unpaired α-chains).[13-15] Simple heterozygosity for certain forms of β-thalassemic hemoglobinopathies can also be associated with a thalassemia intermedia phenotype, sometimes called *dominant β-thalassemia*.[16,17]

Thalassemia minor, also known as β-thalassemia trait or heterozygous β-thalassemia, is caused by the presence of a single β-thalassemia mutation and a normal β-globin gene on the other chromosome. It is characterized by profound microcytosis with hypochromia but mild or minimal anemia.

β-Thalassemia is also called by several other names, including Cooley anemia, Mediterranean anemia, von Jaksch anemia,[1] target cell anemia, erythroblastic anemia, and familial microcytosis.

Molecular Pathology

Forms of β-thalassemia arise from mutations that affect every step in the pathway of globin gene expression: transcription, processing of the mRNA precursor, translation of mature mRNA, and posttranslational integrity of the β-polypeptide chain (Fig. 38-1 and Table 38-1).[18-20] Large deletions removing two or more non–α-genes are found in rare cases, as are smaller partial or total deletions of the β-gene alone (see Fig. 38-1). Most types of β-thalassemia are caused by point mutations affecting one or a few bases. (The original literature for this section is extensive; it is summarized in various publications and databases.[18-25]) Of the more than 200 mutations causing β-thalassemia, approximately 15 account for the vast majority of affected patients, with the remainder responsible for the disorder in only relatively few patients. It has been determined that five or six mutations usually account for more than 90% of the cases of β-thalassemia in a given ethnic group or geographic area (see Table 38-1).[22]

Table 38-1 Common β-Thalassemia Mutations in Different Racial Groups

Racial Group	Description
Mediterranean	IVS-1, position 110 (G → A) Codon 39, nonsense (CAG → TAG) IVS-1, position 1 (G → A) IVS-2, position 745 (C → G) IVS-1, position 6 (T → C) IVS-2, position 1 (G → A)

Transcription

Whereas several mutations alter the promoter region upstream of the β-globin mRNA-encoding sequence, impairing mRNA synthesis, mutations that derange the sequence used as the signal for the addition of the poly-(A) tail of the mRNA (polyadenylation signal[21] have been shown to result in abnormal cleavage and polyadenylation of the nascent mRNA precursor, with resulting reduced accumulation of mature mRNA.[19-21]

Processing

Many forms of β-thalassemia are caused by mutations that impair splicing of the mRNA precursor into mature mRNA in the nucleus or that prevent translation of the mRNA in the cytoplasm. The molecular pathology of splicing mutations is complex (see Fig. 38-1). Some base substitutions ablate the donor (GT) or acceptor (AG) dinucleotides, which are absolutely required at the intron–exon boundaries for normal splicing and thereby completely block production of mature functional messenger RNA. Thus, no β-globin can be synthesized (β°-thalassemia). Other mutations alter the consensus sequences that surround the GT- and AG-invariant dinucleotides and decrease the efficiency of normal splicing signals by 70% to 95%, resulting in β^{+}-thalassemia; some consensus mutations even abolish splicing completely, causing β°-thalassemia. A third type of splicing aberration results from mutations that are not in the immediate vicinity of a normal splice site. These alter regions within the gene, called *cryptic splice sites,* which resemble consensus splicing sites but do not normally sustain splicing (Fig. 38-2). The mutations activate the site by supplying a critical GT or AG nucleotide or by creating a sufficiently strong consensus signal to stimulate splicing at that site 60% to 100% of the time. The activated cryptic sites generate an abnormally spliced, untranslatable mRNA species. Only 10% to 40% of the mRNA precursors are thus spliced at the normal sites, which causes β^{+}-thalassemia of variable severity. The mutation responsible for the most common form of β-thalassemia among Greeks and Cypriots (see Fig. 38-2) activates a cryptic splice site near the 3′ end of the first intron (position 110).[26,27] The determinants that dictate the degree to which each mutation alters splice site use remain largely unknown.

Translation

Mutations that abolish translation occur at several locations along the mature mRNA and are very common causes of β°-thalassemia (see Fig. 38-1 and Table 38-1). The most common form of β°-thalassemia in Sardinians results from a base substitution in the gene that changes

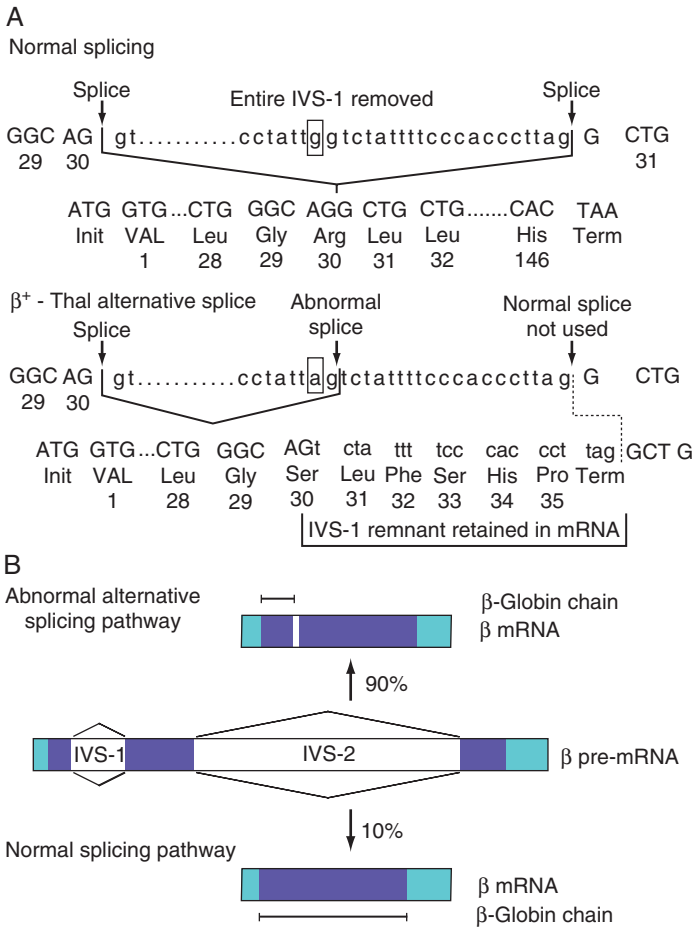

Figure 38-2 β^{+}-THALASSEMIA ARISING FROM ALTERNATIVE MRNA SPLICING CAUSED BY A MUTATION ACTIVATING A CRYPTIC SPLICING SITE. **A**, The G→A mutation is shown enclosed in *squares* located near the 3′ end of intron 1 (IVS-1); it creates a sequence motif closely mimicking a pre-mRNA acceptor splice site. The product of the alternative splicing event is also shown. Note that use of the activated cryptic site generates a mature mRNA that contains an in-frame termination codon and therefore does not encode a functional β-globin chain. (From Benz EJ Jr: The hemoglobinopathies. In Kelly WN, DeVita VT, editors: *Textbook of Internal Medicine,* Philadelphia, 1988, JB Lippincott, p 1423.) **B**, Diagram of the means by which use of the cryptic splice site 90% of the time results in only 10% of the mRNA precursor molecules to be spliced normally into translatable mature mRNA, thus causing β^{+}-thalassemia. *(Adapted from Bunn HF, Forget BG:* Hemoglobin: molecular, genetic and clinical aspects. *Philadelphia, WB Saunders, 1986.)*

the codon encoding the 39th amino acid of the β-globin chain from CAG, which encodes glutamine to TAG, whose equivalent (UAG) in mRNA specifies termination of translation (Fig.38-3).[28,29] A premature termination codon totally abrogates the ability of the mRNA to be translated into normal β-globin. Premature translation termination also results indirectly from frameshift mutations (i.e., small insertions or deletions of a few bases, other than multiples of 3, that alter the phase or frame in which the nucleotide sequence is read during translation).[29] An in-phase premature termination codon is usually encountered within the next 50 bases downstream from a frameshift.

Other Sites

Rare mutations that affect gene function by intriguing mechanisms have been described. An extremely large deletion of the β-globin gene cluster has been described that removes the ε-, γ-, and δ-genes.[30] The patient has a severe β-thalassemia phenotype, but the β-globin gene and 500 bases of adjacent 5′ and 3′ DNA have an entirely normal nucleotide sequence. The β-gene functions normally in surrogate cells. The important aspect of this deletion is that it removes the critical locus control region[18,31] located thousands of bases upstream from the beginning of the globin gene cluster at the 5′ end of the ε-globin gene; loss of this region severely impairs β-gene expression. A number of additional deletions involving the locus control region and various portions of the β-gene cluster, but sparing the β-gene itself, have the same phenotype.[1,2,19-21] In other cases of β-thalassemia, the β-gene and adjacent DNA are structurally normal, and the basis of abnormal gene expression is unknown.[22]

Relationship Between Specific Mutations and Clinical Severity

The relationship between an individual mutation and the clinical severity of the β-thalassemia phenotype associated with that particular mutation is complex.[22] For example, the A to G mutation at position -34 of the β-gene promoter commonly encountered in black patients is associated with a different clinical severity than that found in Chinese patients inheriting the same mutation.[32] Clearly, the genetic "context" of the mutation is different in the two populations. The mutant β-globin gene in the two different racial groups probably arose in different chromosome backgrounds that have different potentials for γ-gene expression, as discussed in the following paragraph.

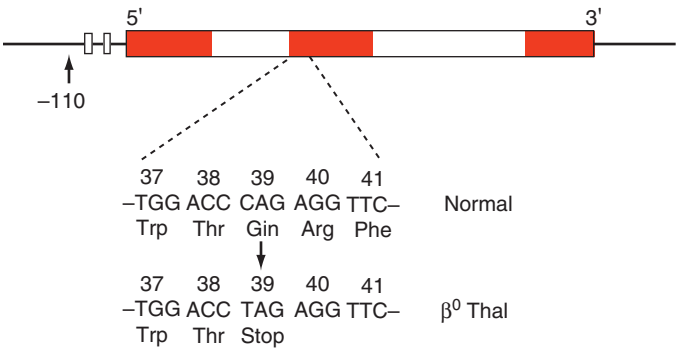

Figure 38-3 β°-THALASSEMIA ARISING FROM A MUTATION CHANGING AN AMINO ACID CODON TO A TERMINATION CODON (NONSENSE MUTATION). *(Adapted from Takeshita K, Forget BG, Scarpa A, Benz EJ Jr: Intranuclear defects in b-globin mRNA accumulation due to a premature translation termination codon.* Blood *64:13, 1984.)*

Multiple forms, or haplotypes, of normal non–α-globin gene clusters exist in various human populations. These are defined by the patterns of restriction fragment length polymorphisms[28] detected when DNA is digested with restriction endonucleases and analyzed by Southern gene blotting for the fragments bearing the non–α-globin genes. Haplotypes differ according to whether each restriction site is present or absent along the gene cluster. More than 12 haplotypes have been defined by examination of several restriction sites located along the cluster that are present or absent in a polymorphic manner in normal individuals.[28] The clinical variability encountered in two different groups bearing identical primary mutations correlates best with the haplotype or chromosome background on which the mutation is inherited. The differences in physiologically important functions among haplotypes that modulate severity remain unknown, but a possible explanation lies in the variable abilities of the γ-globin genes on different chromosomes to respond to severe erythroid stress by increased expression during postnatal life. The β-globin genes carried on some haplotypes differ in the degree to which they can respond in this manner.[33] Because Hb F synthesis reduces the severity of β-chain hemoglobinopathies,[1] the level of γ-gene expression from a given chromosome can play an important modulating role.

Pathophysiology

The biochemical hallmark of β-thalassemia is reduced biosynthesis of the β-globin subunit of Hb A ($\alpha_2\beta_2$). In β-thalassemia heterozygotes, β-globin synthesis is about half-normal (β/α synthetic ratio, 0.5-0.7). In homozygotes for β°-thalassemia, who account for approximately one-third of patients, β-globin synthesis is absent. β-globin synthesis is reduced to 5% to 30% of normal levels in β^+-thalassemia homozygotes or β^+/β°-thalassemia compound heterozygotes, who together account for approximately two-thirds of cases.[1]

Because the synthesis of Hb A ($\alpha_2\beta_2$) is markedly reduced or absent, the RBCs are hypochromic and microcytic. γ-Chain synthesis is partially reactivated so that the hemoglobin of the patient contains a relatively large proportion of Hb F.[1] However, these γ-chains are quantitatively insufficient to replace β-chain production.

In heterozygotes (β-thalassemia trait), relatively little α-globin accumulation occurs. Output from the single normal β-globin gene supports substantial Hb A formation, thus preventing harmful accumulation of excess α-globin chains. Thus, one encounters hypochromia with microcytosis but relatively little evidence of anemia, hemolysis, or IE.

Individuals inheriting two β-thalassemic alleles experience a more profound deficit of β-chain production. Little or no Hb A is produced; more importantly, the imbalance of α- and β-globin production is far more severe (Fig. 38-4). The limited capacity of RBCs to proteolyze the excess α-globin chains, a capacity that probably exerts a protective effect in heterozygous β-thalassemia, is overwhelmed in homozygotes. Free α-globin accumulates, and unpaired α-chains aggregate and precipitate to form inclusion bodies, which cause oxidative membrane damage within the RBC[34] and destruction of immature developing erythroblasts within the BM IE.[35] Consequently, relatively few of the erythroid precursors undergoing erythroid maturation in the BM survive long enough to be released into the bloodstream as erythrocytes. The occasional erythrocytes that are formed during erythropoiesis bear a burden of inclusion bodies. The reticuloendothelial cells in the spleen, liver, and BM remove these abnormal cells prematurely, producing a hemolytic anemia.

Defective β-globin synthesis exerts at least three distinct yet interrelated effects on the generation of oxygen-carrying capacity for the peripheral blood (see Fig. 38-4): (1) IE, which impairs production of new RBCs; (2) hemolytic anemia, which shortens the survival of the few RBCs produced; and (3) hypochromia with microcytosis, which reduces the oxygen-carrying capacity of the few RBCs that do survive.

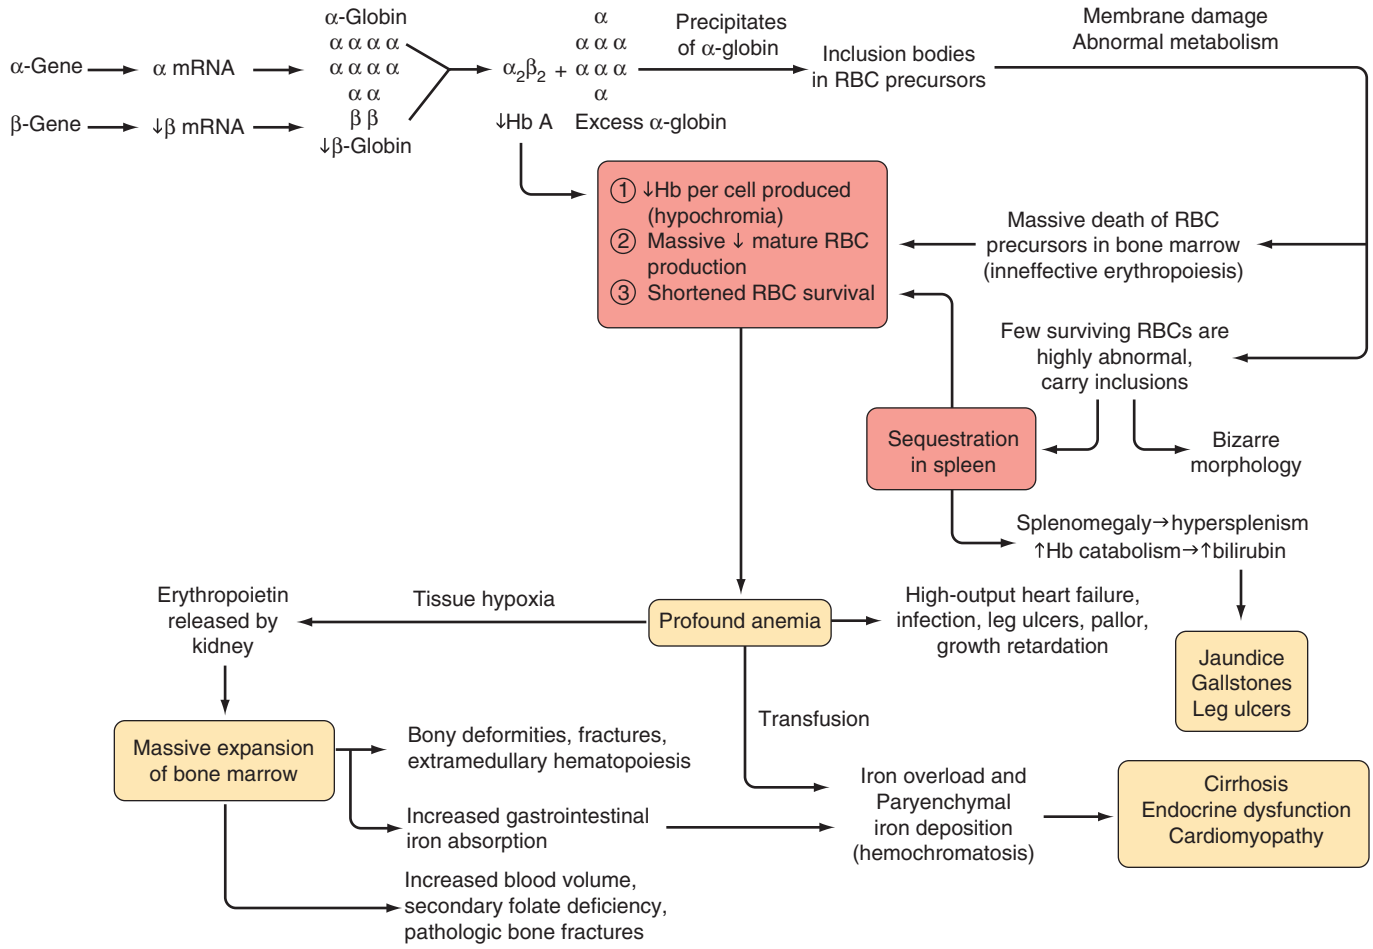

Figure 38-4 PATHOPHYSIOLOGY OF SEVERE FORMS OF β-THALASSEMIA. The diagram outlines the pathogenesis of clinical abnormalities resulting from the primary defect in β-globin chain synthesis. *RBC,* Red blood cell.

In the most severe forms of the disorder, these three factors conspire to produce a catastrophic anemia complicated by the effects of exuberant hemolysis.

The profound deficit in the oxygen-carrying capacity of the blood stimulates production of high levels of erythropoietin in an attempt to promote compensatory erythroid hyperplasia. Unfortunately, the ability of the BM to respond positively is markedly impaired by IE. Massive BM expansion does occur, but very few erythrocytes are actually supplied to the circulation. The BM becomes packed with immature erythroid precursors, which die from their burden of precipitated α-globin chains before they reach the reticulocyte stage. Profound anemia persists, driving erythroid hyperplasia to still higher levels. In some cases, erythropoiesis is so exuberant that masses of extramedullary erythropoietic tissue form in the chest, abdomen, or pelvis.

As described in the following section, massive BM expansion exerts numerous adverse effects on the growth, development, and function of critical organ systems and creates the characteristic facies caused by maxillary BM hyperplasia and frontal bossing (Fig. 38-5). Hemolytic anemia results in massive splenomegaly and high-output congestive heart failure. In untreated cases, death occurs during the first 2 decades of life. Treatment with RBC transfusions sufficient to maintain hemoglobin levels above 9.0 to 10.0 g/dL improves oxygen delivery, suppresses the excessive IE, and prolongs life. Unfortunately, as discussed in more detail later, complications of chronic transfusion therapy, including iron overload, can be fatal before 30 years of age. The addition of iron chelation therapy to regular transfusion therapy now prolongs survival and improves the quality of life.

Figure 38-5 THALASSEMIC FACIES. See text for description. *(From Jurkiewicz MJ, Pearson HA, Furlow LT Jr: Reconstruction of the maxilla in thalassemia.* Ann N Y Acad Sci *165:437, 1969.)*

PATHOPHYSIOLOGY: NEW FINDINGS, THE ROLE OF JAK2 AND HEPCIDIN IN β-THALASSEMIA

IE is the hallmark of β-thalassemia, triggering a cascade of compensatory mechanisms and resulting in clinical sequelae such as erythroid BM expansion, extramedullary hematopoiesis, splenomegaly, and increased gastrointestinal iron absorption. Several studies demonstrate that erythropoietic iron demand influences hepcidin expression to a greater degree than anemia or non-hematopoietic iron stores.[36,37] In particular, studies in β-thalassemia demonstrate that hepcidin expression is disproportionally low relative to the degree of iron overload.[38-40] (see Chapter 33). Recent studies in mice have begun to shed light on the complex molecular mechanisms underlying IE and the associated compensatory pathways; this new understanding may lead to the development of novel therapies. Increased or excessive activation of the Janus kinase 2 (JAK2)–STAT5 (signal transducers and activators of transcription 5) pathway promotes unnecessary disproportionate proliferation of erythroid progenitors, but other factors suppress serum hepcidin levels leading to dysregulation of iron metabolism. Preclinical studies suggest that JAK2 inhibitors, hepcidin agonists, and exogenous transferrin may help to restore normal erythropoiesis and iron metabolism and reduce splenomegaly[41-51] (see boxes on JAK2, Hepcidin, and Transferrin).

Clinical Manifestations

Clinical Findings at Diagnosis

Protected by prenatal Hb F production, infants with β-thalassemia major are born free of significant anemia. Nevertheless, deficient β-chain synthesis can be demonstrated at birth. Clinical manifestations usually emerge during the second 6 months of life as the consequences of defective β-globin synthesis on overall hemoglobin production become more pronounced. The diagnosis is almost always evident by 2 years of age.[90] Pallor, irritability, growth retardation, abdominal swelling caused by enlargement of the liver and spleen, and jaundice are the usual presenting features.[91] Facial and skeletal changes caused by BM expansion develop later.

Clinical Findings in Untreated or Undertreated Patients

Untreated patients die in late infancy or early childhood as a consequence of severe anemia. In a retrospective review from Italy, the average survival of children with untreated thalassemia major was less than 4 years; approximately 80% died in the first 5 years of life.[92] Patients who receive transfusions sporadically may live somewhat longer than untransfused patients, but their quality of life is extremely poor as a result of both the chronic anemia and the IE. The low hemoglobin level and massive organomegaly are usually disabling, and the changes in the facial bones are disfiguring. After 10 to 20 years of weakness, stunted growth, and impaired activity, the undertransfused patients usually succumb to congestive heart failure.

This disastrous symptom constellation, so prevalent in the past, is now rare in North America and most industrialized countries. Nonetheless, the clinical manifestations and complications of untreated or undertreated β-thalassemia major illustrate the principles of the pathophysiology. Furthermore, these descriptions accurately characterize the disease that is still prevalent in many parts of the world.

Initial Laboratory Findings

The anemia of thalassemia major is characterized by severe hypochromia and microcytosis. The hemoglobin level decreases progressively

JAK2

In murine models and patients with β-thalassemia, erythroid precursors express elevated levels of the phosphorylated active form of JAK2 (pJAK2) and other downstream signaling molecules that promote proliferation and inhibit differentiation of erythroid progenitor cells (see Fig. 38-3).[52,53] A recent study showed that JAK2 activation upregulated the transcription factor ID1[54]; high levels of ID1 have been found to inhibit cellular differentiation.[53] JAK2 signaling also activates the phosphoinositol-3-kinase (PI3K)–AKT pathway, which plays an important role in regulating cell survival and the activity of the transcription factor forkhead box O3 (FOXO3), which modulates oxidative stress during erythropoiesis.[53] Taken together, findings from these studies suggest a model in which persistent phosphorylation of JAK2 as a consequence of high erythropoietin (EPO) levels induces erythroid hyperplasia and massive extramedullary hematopoiesis and the early erythroid progenitors that fail to differentiate colonize and proliferate predominantly in the spleen and liver,[52] thus contributing to hepatosplenomegaly. Given the central role of JAK2 in the pathophysiology of ineffective erythropoiesis (IE), it has been hypothesized that JAK2 inhibitors may be effective in modulating some of these compensatory mechanisms that lead to the severe clinical complications associated with β-thalassemia.

The activation of the EPO–EPO-Receptor–JAK2 pathway is not likely the only cause of the limited erythroid differentiation observed in β-thalassemia. It is possible that other factors or abnormal physiologic conditions present in β-thalassemia come into play, interfering with erythroid cell differentiation. Among the possible factors acting together with JAK2, iron overload, reactive oxygen species (ROS), or the unbalanced synthesis of globin chains or heme can be also considered.[55] Iron is essential for all cells but is toxic in excess. It is possible to speculate that thalassemic erythroid cells accumulate an excess of toxic heme associated with free α-chains, leading to the formation of ROS, which has been involved with cell RBC hemolysis and altered differentiation.[56,57]

Serum iron is bound to transferrin and enters erythroid cells primarily via receptor-mediated endocytosis of the transferrin receptor (TfR1). TfR1 is essential for developing erythrocytes, and reduced TfR1 expression is associated with anemia. *STAT5*-null mice are severely anemic and die perinatally. Two studies associated STAT5 to iron homeostasis showing that ablation of STAT5 leads to a dramatic reduction in the iron regulatory protein 2 (IRP-2) and *Tfr1* mRNA and protein.[58,59] Both genes were demonstrated to be direct transcriptional targets of STAT5, establishing a clear link between EPO-R–JAK2–STAT signaling and iron metabolism. Therefore, it is possible that activation of JAK2 might increase erythroid iron intake and that this might be detrimental in thalassemic cells, in which part of the iron ends up in toxic hemichromes (α-chain/heme aggregates), triggering ROS formation.

The persistent phosphorylation of JAK2 leads to an increased number of surviving erythroid precursors, contributing to the IE. Therefore, suppression of JAK2 activity may modulate IE. Based on this hypothesis, a JAK2 inhibitor was utilized for 10 days in mice affected by thalassemia intermedia (Hbbth3/+) and demonstrated a reduction in splenomegaly ("nonsurgical splenectomy").[52] This study also demonstrated that JAK2 inhibitors decreased the number of cells expressing cell cycle–related genes and partially reversed the IE, ameliorating the ratio between erythroid precursors and enucleated RBCs.[52,60] Thus, although a complete understanding of how JAK2 inhibitors achieve this effect is unavailable, modulation of cell cycle and differentiation are likely involved.

Hepcidin

Iron absorption and recycling are regulated by the peptide hormone hepcidin, the main regulator of body iron flows. Hepcidin exerts its function by binding to the only known iron export protein, ferroportin (FPN-1), found on all cells involved in iron metabolism; binding FPN-1 results in its internalization, degradation, and cessation of iron export.[61] Regulation of hepcidin is influenced by iron, hypoxia, inflammation, and erythropoiesis, possibly through distinct mechanisms. In the recent past, major advances have been made in understanding the molecular mechanism of hepcidin regulation.[62] In short, in the liver, the bone morphogenic protein (BMP) pathway plays a central role in hepcidin regulation by iron.[63,64] When BMP6 and hemojuvelin (HJV) interact with BMP receptors type I/II, phosphorylation and activation of the small mothers against decapentaplegic (SMAD) complex results in increased hepcidin expression.[65] Additionally, holo-Tf regulates hepcidin expression through TfR2 and HFE. Holo-Tf binds both TfR1 and TfR2, although it has a stronger affinity for TfR1. In a proposed model, HFE associates with TfR1 under low iron conditions and is displaced when TfR1 binds holo-Tf.[66-68] As serum iron and holo-Tf concentrations rise, the ratio of TfR2 to TfR1 expression increases. Together, this leads to TfR2/holo-Tf membrane stabilization and induces HFE/TfR2 binding and hepcidin expression.[69,70] Mutations in many of these genes are central to the pathophysiology of hereditary hemochromatoses (HH) in which insufficient hepcidin expression is a common feature (reviewed elsewhere).[71]

Several studies demonstrate that erythropoietic iron demand influences hepcidin expression to a greater degree than anemia or nonhematopoietic iron stores.[36,37] In particular, studies in β-thalassemia demonstrate that hepcidin expression is disproportionally low relative to the degree of iron overload.[38-40] These and previous studies proposed that an "erythroid factor" suppresses hepcidin synthesis.[72] This "erythroid regulator" is likely a factor secreted either from immature and proliferating or dying erythroid precursors. If this factor is secreted by immature erythroid precursors, it would be present in all conditions in which erythroid precursor expansion occurs (e.g., after recovery from phlebotomy and transient anemia in blood donors).[73,74] Twisted gastrulation-1 (TWSG1) has been isolated from immature erythroid precursors in β-thalassemic mice.[75] As a small secreted cysteine-rich protein able to influence BMPs signaling, the expression of TWSG1 is increased in β-thalassemic mice and represses hepcidin in vitro.[75,76] However, whether this factor is present in other conditions and how efficiently TWSG1 represses hepcidin in physiologic conditions are still unclear. If the proposed "erythroid factor" is secreted by dying erythroid precursors, it would be present only in conditions in which large numbers of erythroid precursors undergo apoptosis. Growth differentiation factor-15 (GDF15) has been isolated from the sera of β-thalassemic patients and in other individuals exhibiting features of IE, such as MDS and congenital dyserythropoietic anemia type I and II and an inverse correlation with hepcidin levels has been demonstrated.[77-79] GDF15 is a member of the TGF-β superfamily of proteins, which are known to control cell proliferation, differentiation, and apoptosis in numerous cell types. However, it is possible that in conditions such as β-thalassemia, multiple "erythroid factors" suppress hepcidin expression.[80,81] The mechanisms of action of GDF15 and TWSG1 in repressing hepcidin expression remain undefined but are likely to alter the function of proteins that modulate hepcidin production.

Based on these and previous observations, it has been postulated that in β-thalassemic patients, more iron is absorbed than required for erythropoiesis. Thus, decreasing dietary iron intake or hepcidin administration might prevent iron overload. In fact, mice affected by thalassemia intermedia (Hbb*th3*/+) avoid iron overload when placed on a low-iron diet or are engineered to overexpress a moderate level of hepcidin.[82] Reversal of iron overload results in reduced erythroid iron intake, limiting the synthesis of heme and the formation of hemichromes and reactive oxygen species.[82] Because hemichromes and ROS cause IE in ß-thalassemia, iron restriction and decreased erythroid iron intake result in more effective erythropoiesis, normalize RBC morphology and lifespan, increase circulating Hb, and reverse splenomegaly.[60,82] Thus, the use of hepcidin agonists or drugs that increase hepcidin expression decreases iron uptake from the diet, reduces iron overload, and improves erythropoiesis in TI.[82] In TM, repeated blood transfusions are the principal cause of iron overload. Despite iron overload, hepcidin concentrations are low; transfusion also suppresses endogenous erythropoiesis and, as a consequence, results in a transient increase in hepcidin.[38,83,84] Although intestinal iron absorption contributes part of the total iron load in these patients, hepcidin therapy may be effective in conjunction with transfusion to prevent intestinal iron uptake when endogenous hepcidin falls.

Transferrin

Iron directed to the erythroid compartment is restricted to Tf-bound iron, and its relationship with TfR1 is well established.[85] Tf takes up iron from duodenal enterocytes (when it is absorbed) and from macrophages (when iron is recycled from senescent RBCs). The amount of iron delivered to each erythroid precursor depends on the amount of monoferric- and holo-Tf found in circulation as well as the density of TfR1 on the cell surface. Typically, each erythroid precursor has more than 1 million TfR1s on its membrane because of its large iron requirement, greater than all other cell types.[86] Iron uptake starts when holo-Tf binds TfR1. Under normal circumstances, the affinity of TfR1 for holo-Tf is greater than for monoferric-Tf. However, this greater affinity wanes as the iron supply is diminished.[87] Monoferric-Tf is the predominant form of Tf in circulation when Tf saturation is lowered.[88] Each molecule of monoferric-Tf delivers less iron to erythroid precursors than holo-Tf.[87] This enables a greater number of erythroid precursors to receive a smaller portion of the iron pool to offset developing anemia and is consistent with a low MCV and MCH.

Transferrin receptor takes up iron from duodenal enterocytes where iron is absorbed and from macrophages when iron is recycled from senescent RBCs and delivers it to cells by binding TfR1. Tf saturation is the main player in determining the rate of erythroid iron intake, modulating erythropoiesis. In turn, erythropoiesis influences hepcidin expression in the liver. Therefore, reducing the saturation levels of Tf might have beneficial effects in β-thalassemia, decreasing formation of hemichromes in the RBCs as well as the florid erythropoiesis that suppresses hepcidin expression in the liver. In fact, chronic treatment with apo-Tf injections in *Hbbth1/th1* mice (another murine model of thalassemia intermedia) results in increased Hb production, decreased reticulocytosis and serum EPO levels, reverses splenomegaly, and elevates hepcidin expression.[89] Apo-Tf injections reduce hemichrome formation and change the proportion of erythroid precursors to more mature relative to immature precursors, lower the rates of apoptosis in mature erythroid precursors, and reduce the amount of extramedullary erythropoiesis in the liver and spleen in *Hbbth1/th1* mice. These observations suggest that addition of exogenous apo-Tf results in decreased Tf saturation and likely a shift toward more monoferric-Tf molecules with more Tf molecules available to deliver smaller amounts of iron to more erythroid precursors, resulting in further decreased MCH and fewer hemichromes. However, how additional apo-Tf is able to improve erythropoiesis in *Hbbth1/th1* mice is incompletely understood.

during the first months of life. When the child becomes symptomatic, the hemoglobin level may be as low as 3 to 4 g/dL. RBC morphology is strikingly abnormal, with many microcytes, bizarre poikilocytes, teardrop cells, and target cells (Fig. 38-6). A characteristic finding is the presence of extraordinarily hypochromic, often wrinkled and folded cells (leptocytes) containing irregular inclusion bodies of precipitated α-globin chains (see box on Clinical Heterogeneity of Thalassemia).

Nucleated RBCs are frequently present. The reticulocyte count is 2% to 8% lower than would be expected in view of the extreme erythroid hyperplasia and hemolysis. The low count reflects the severity of intramedullary erythroblast destruction. The white blood cell count is elevated. A moderate polymorphonuclear leukocytosis and normal platelet count are typical unless hypersplenism has developed. The BM exhibits marked hypercellularity caused by erythroid hyperplasia. The RBC precursors show defective hemoglobinization and reduced amounts of cytoplasm.

The osmotic fragility is strikingly abnormal. The RBCs are so markedly resistant to hemolysis in hypotonic sodium chloride solution that some are not entirely hemolyzed even in distilled water. Before transfusion therapy is initiated, the serum iron and transferrin saturation are already increased as a result of increased iron absorption.[93]

The hemoglobin profile reveals predominantly Hb F. In patients with homozygous β°-thalassemia, no Hb A is found throughout life. Hb A may be undetectable in the newborn with β^+-thalassemia and is present in reduced amounts in later life. The levels of Hb A_2 in thalassemia major are variable, probably because of increased numbers of F cells that have a decreased Hb A_2 content.[1] Other biochemical abnormalities of the RBC in cases of thalassemia major include a postnatal persistence of the i antigen and a decrease of RBC carbonic anhydrase; these findings are probably also caused by the elevated levels of circulating F cells.

The intraerythrocytic inclusions in the peripheral blood cells of patients with thalassemia, first described by Fessas,[94] are especially prominent after splenectomy. These inclusions, best seen by staining with methyl violet or by phase microscopy, are aggregates of precipitated, denatured α-chains.[95] They are also found in large numbers within erythroid precursors in the BM.

The serum is icteric; unconjugated bilirubin levels are in the range of 2.0 to 4.0 mg/dL at the time of diagnosis but may rise substantially as the anemia worsens in the absence of transfusion. RBC survival in cases of thalassemia major is variable but usually markedly decreased. The ^{51}Cr half-life ranges between 6.5 and 19.5 days compared with the normal half-life of 25 to 35 days.[35] Increased plasma iron turnover and poor use of radiolabeled iron indicate IE.[35] Serum aspartate aminotransferase levels are frequently increased at diagnosis because of hemolysis. Alanine aminotransferase levels are usually normal before transfusion therapy but may rise subsequently because of iron-induced hepatic damage or viral hepatitis. Lactate dehydrogenase levels are markedly elevated as a consequence of IE. Haptoglobin and hemopexin are reduced or absent.[96]

Clinical Heterogeneity of Thalassemia

The severity of β-thalassemia is remarkable for its variability in different patients. Two siblings inheriting identical thalassemia mutations sometimes exhibit markedly different degrees of anemia and erythroid hyperplasia. Many factors contribute to this clinical heterogeneity. Individual alleles vary with respect to severity of the biosynthetic lesion. Other modifying factors ameliorate the burden of unpaired α-globin. High levels of Hb F expression persist to widely various degrees in β-thalassemia. Because γ-globin can substitute for β-globin, simultaneously generating more functional hemoglobins and reducing the α-globin inclusion burden, this is a powerful modulating factor. Theoretically, patients may also vary in their ability to solubilize unpaired globin chains by proteolysis. Occasional heterozygous patients have had more severe anemia than expected, possibly because of defects in these proteolytic systems or because of the type of thalassemic mutation. Inheritance of more than the usual complement of α-globin genes may also increase with severity of β-thalassemia because of additional production of unpaired α-globin chains. All of these factors emphasize the essential role of α-globin inclusions in the pathophysiology of β-thalassemia.

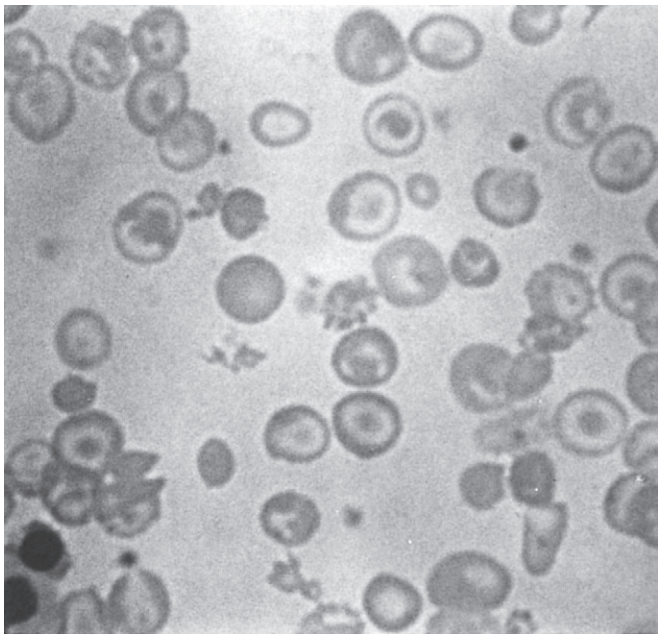

Figure 38-6 MORPHOLOGIC APPEARANCE OF THE PERIPHERAL BLOOD FILM IN A CASE OF SEVERE β-THALASSEMIA. Note the many bizarre cells, the hypochromia, nucleated red blood cells, target cells, and leptocytes. *(From Pearson HA, Benz EJ Jr: Thalassemia syndromes. In Miller DR, Baehner RL, McMillan CW, editors:* Smith's blood diseases of infancy and childhood, *ed 5, St. Louis, 1984, CV Mosby, p 439.)*

Later Laboratory Findings

Serum zinc levels may fall to abnormally low levels. A relationship between this finding and growth failure has been postulated but not established.[97,98] Low levels of plasma and leukocyte ascorbic acid are common in thalassemic patients because of increased metabolism of the vitamin to oxalic acid in the presence of iron overload.[99,100] Biochemical evidence of folic acid deficiency may occur as a result of excessive consumption secondary to increased requirements.[101,102] The serum levels of α-tocopherol are often reduced to less than 0.5 mg/dL, and increased RBC membrane lipid peroxidation has been described.[103-105]

Coagulation abnormalities consistent with liver disease (i.e., lowered levels of factors II, V, VII, IX, and X) may occur in older patients with hepatitis or iron-induced hepatic injury.[106] Only rarely are the abnormalities sufficient to require specific therapy. However, the combination of mild thrombocytopenia from hypersplenism and low coagulation factors and platelet dysfunction from liver disease may cause or aggravate bleeding.[107]

Numerous laboratory abnormalities reflect the accumulation of excessive iron and the consequences of iron-induced organ damage, and they are described in the following sections.

Treatment

The advent of modern therapy has had a major impact on the clinical and laboratory features of thalassemia major. Transfusion and chelation therapy, described subsequently in detail, have ameliorated many

of the most striking manifestations of the disease. Bone marrow transplantation (BMT) has allowed for the cure of a select few. However, these therapies have created their own complications; therefore, this section addresses the treatment of the complications of thalassemia and its therapy. Current clinical management and associated clinical manifestations and complications have been reviewed in a number of publications.[108-113]

Transfusion Therapy

Transfusion therapy for thalassemia was once sparingly administered as a palliative measure when patients became symptomatic. These periodic transfusion regimens were unsatisfactory even for those limited purposes; symptoms of anemia and the cosmetic and other consequences of overgrowth of erythropoietic tissue rendered life unpleasant and uncomfortable for patients. Consequently, several centers initiated transfusion programs in which patients received regular transfusions to keep their hemoglobin levels high enough to ameliorate these symptoms,[114,115] but the median survival time of patients transfused to maintain hemoglobin levels of 7 to 8 g/dL in the United States in the 1960s was only 17 years of age.[115,116] These "hypertransfusion" programs were designed initially to maintain hemoglobin levels above 8 g/dL. In the more modern application of hypertransfusion therapy, hemoglobin levels are usually maintained above 9 to 10.5 g/dL.

The clinical benefits of hypertransfusion programs are dramatic. The growth of younger children follows normal percentiles for height and weight.[117] Erythropoiesis is partially but substantially suppressed as evidenced by decreased numbers of reticulocytes and normoblasts and transferrin receptor levels.[118,119] Hypertransfusion reduces or prevents the enlargement of the liver and spleen. Abnormal facies and bone fractures occur less frequently. The overall sense of well-being allows normal age-appropriate activities[120,121] (see box on Guidelines for Transfusion Therapy).

A more vigorous transfusion program (supertransfusion) aimed at keeping hemoglobin levels above 12.0 g/dL is no longer recommended.[122] This approach rested on the assumption that the benefits of further suppression of erythropoiesis and gastrointestinal iron absorption will offset the increased need for RBCs. However, several, although not all, studies have demonstrated that transfusion requirements (and therefore the rates of transfusional iron loading) increase as the hemoglobin level is raised (Fig. 38-7).[117,123,124] As a result, the consistent maintenance of hemoglobin levels above 11 or 12 g/dL is generally reserved for patients with poor tolerance of lower hemoglobin levels because of cardiac disease or other reasons.

Alternative approaches to conventional transfusion therapy have been proposed in an effort to reduce the rate of transfusion iron loading. These approaches have generally relied on the concept that younger RBCs (neocytes) will circulate longer in the recipient than older RBCs. Preclinical experiments based on the difference in density between younger and older RBCs established the validity of this approach.[125,126] However, in prospective clinical trials, blood requirements were reduced only by 13% to 20%.[127-129] This reduction in iron loading did not outweigh the disadvantages of neocyte transfusions that included increased cost, wastage of 50% of the donor RBCs, and increased donor exposures. The use of automated exchange transfusion has been proposed as another approach to reducing iron loading in patients with thalassemia.[130] With this method, RBCs are removed from the patient at the same time that new donor RBCs are transfused. This approach has been applied successfully to transfusion therapy for sickle cell disease. However, the goal of transfusion therapy in sickle cell disease is the replacement of Hb S–containing RBCs with Hb A–containing RBCs irrespective of the total hemoglobin level. In contrast, the goal of transfusion therapy in patients with thalassemia is to maintain a specific total hemoglobin level. Despite these different goals, studies of automated exchange transfusion in patients with thalassemia have demonstrated a reduction in net RBC requirements of 30% to 50%, either by reducing the amount of blood administered at the usual transfusion interval or by prolonging the interval between transfusions.[130,131] The benefits of this approach are probably attributable to the removal of previously transfused RBCs from the patients and replacement with younger, recently donated RBCs, reducing the overall age of the circulating RBC population. Further clinical trials of automated exchange transfusion in thalassemia are currently underway.

The decision to initiate transfusion therapy should take into account the overall clinical condition of the patient as well as the hemoglobin level. Patients with severe and persistent anemia (hemoglobin <6-7 g/dL) usually also have failure to thrive, decreased activity level, and irritability. For these patients, transfusion therapy should begin after confirmation of the diagnosis of thalassemia and after demonstration that acute factors such as a febrile illness or folic acid deficiency are not confounding the assessment of the severity of anemia. For patients with higher hemoglobin levels, the decision to begin transfusion depends on the careful assessment of the child's clinical findings. For example, some children with thalassemia have early and pronounced facial bone deformities caused by BM expansion despite a hemoglobin level of 8 g/dL or higher. For such children, the benefits of transfusion therapy may outweigh the risks. In contrast, some patients with thalassemia have little or no clinical difficulty despite a persistent hemoglobin level of 7 to 8 g/dL, and the benefits of transfusion therapy may be small. Determination of

Guidelines for Transfusion Therapy

Although some of the details of a transfusion program for patients with thalassemia major vary from center to center, the following guidelines are important for achieving the benefits while controlling the risks of a transfusion program. The rationales for these guidelines are discussed in the text.

1. Obtain a complete RBC antigen profile before the first transfusion.
2. Administer 10 to 15 mL/kg of RBCs every 2 to 4 weeks to maintain the pretransfusion hemoglobin level above 9 to 10.5 g/dL.
3. Use leukoreduced RBCs that have been stored for less than 7 to 10 days.
4. Avoid the use of first-degree relatives as blood donors.
5. For patients who come to a new center after receiving transfusions elsewhere, contact the previous blood bank for information about alloantibodies.

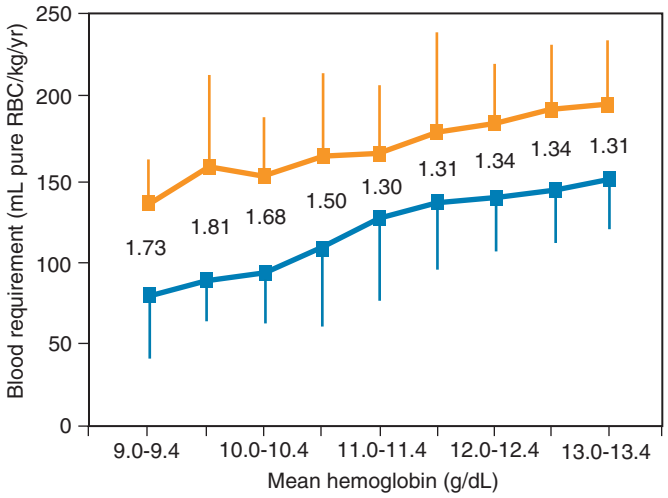

Figure 38-7 Relationship between transfusion requirements and mean hemoglobin level maintained by patients with thalassemia major. *(Adapted from Rebulla P, Modell B: Transfusion requirements and effects in patients with thalassemia major.* Lancet *337:277, 1991.)*

Deciding to Begin Transfusion Therapy in Patients With Thalassemia

The decision to initiate regular RBC transfusions is one of the most important—and sometimes most difficult—steps in the management of patients with thalassemia. Regular RBC transfusions not only distinguish thalassemia major from thalassemia intermedia but also commit the patient to long-term chelation therapy to control the transfusional iron loading. The decision should include consideration of both clinical and laboratory findings. Children who are growing poorly and developing disfiguring bone changes will benefit from regular transfusions even if their hemoglobin levels are 8 to 9 g/dL. On the other hand, children who are asymptomatic at hemoglobin levels of 7 to 8 g/dL may have little to gain from transfusions. Hemoglobin levels below 7 g/dL are usually associated with problems related to both the anemia and the compensatory erythropoiesis. When the hemoglobin level is consistently less than 7 g/dL, there is usually little to be gained from delaying transfusion.

genotype may provide some guidance by distinguishing patients with more severe defects in β-globin production from those with less severe defects, but the overlap between genotype and phenotype in thalassemia still requires reliance on clinical assessment (see box on Deciding to Begin Transfusion Therapy in Patients With Thalassemia).

Before the first blood transfusion is given to a child with thalassemia major, a complete RBC antigen profile should be obtained. This information is valuable for identifying minor blood group incompatibility if alloimmunization develops later and helps to distinguish alloantibodies from autoantibodies. The value of extended matching of donor RBCs has not been established in cases of thalassemia, but experience with sickle cell disease suggests that matching for the full Rh system as well as the Kell antigen may reduce the rate of alloimmunization.

In practice, the goal of maintaining the hemoglobin level above 9 to 10.5 g/dL is usually achieved by administration of approximately 15 mL/kg/mo or 1 to 2 units of donor RBCs every 2 to 5 weeks. Patients with heart disease may need smaller aliquots of RBCs at more frequent intervals to prevent problems related to volume overload. In general, patients can receive the entire unit of donor packed RBCs. However, fractional units are appropriate for infants, small patients, and older patients with heart disease. With the use of current additive solutions, the duration of storage of donor RBCs has only a small effect on the 24-hour recovery and the survival of the RBCs in each transfused unit. However, for patients with thalassemia major who undergo transfusion every 2 to 5 weeks, these small differences may have a significant impact on the annual consumption of blood. Consequently, the use of donor RBCs that have been stored for less than 7 to 10 days strikes a reasonable balance between the potential reduction in transfusion iron loading and the efficient use of the blood bank inventory. The use of volunteer blood donors remains the standard for patients with thalassemia. Although some families of children with thalassemia prefer directed donations, this approach has not reduced the rate of transfusion-transmitted infections among blood recipients in general and has not been shown to reduce the rate of alloimmunization in thalassemia. If directed donations are used, close relatives should be avoided because stem cell transplantation may be a later therapeutic option.

At present, the blood product of choice for patients with thalassemia is filtered RBCs, although some centers use filtered and washed RBC transfusions to prevent the recurrence of febrile or urticarial reactions.[132] Febrile reactions occur less commonly than in the past as a result of the use of leukoreduced donor RBCs. If such reactions occur despite the use of filtered blood products, additional measures include pretransfusion therapy with acetaminophen and the use of washed or frozen-thawed RBCs. Urticarial and other allergic reactions can usually be managed with antihistamine therapy or, when persistent, pretransfusion administration of corticosteroids. Frozen-thawed RBCs are primarily useful for patients with multiple antibodies who require donor RBCs with rare phenotypes that must be collected and stored well in advance of the actual transfusion.

Red blood cell alloimmunization occurs in 3% to 23% of patients with thalassemia major.[124,132-135] If blood donors and recipients come from different ethnic backgrounds with different RBC antigen profiles, as in some North American thalassemia centers, the risk of alloimmunization is increased.[136] New alloantibodies may be clinically silent, associated with increasing transfusion requirements, or accompanied by signs of active hemolysis such as increasing jaundice and dark urine. As noted earlier, the use of extended antigen matching may help prevent alloimmunization. Initiation of transfusion therapy before the age of 3 years may also be associated with a lower risk of this complication.[124,135,137] Patients with a history of alloantibodies require particular attention when receiving a transfusion at a new hospital because the serologic studies may fail to detect a clinically significant antibody that is present in low amounts. A review of the blood bank records from the previous institutions is essential in choosing the appropriate RBC product.

Autoantibodies also occur in patients with thalassemia major, usually, but not always, after the development of an alloantibody.[138] A subset of patients with autoantibodies has a clinically important autoimmune hemolytic anemia that leads to the premature destruction of donor cells as well as destruction of the patient's own RBCs. Transfusion requirements are markedly increased, and further transfusion therapy may be impossible for some patients. Treatment with corticosteroids, other immunosuppressive therapy, or intravenous gamma globulin may improve RBC survival in some cases.

A syndrome of posttransfusion hypertension, convulsions, and cerebral hemorrhage has also been reported.[139] The mechanism underlying this complication is uncertain but is possibly related to large changes in hemoglobin level at the time of transfusion. These reactions are uncommon in conventional transfusion programs.

The potential impact of transfusion-transmitted infections on patients with thalassemia major is demonstrated by the high prevalence of human immunodeficiency virus (HIV) infection in certain thalassemia centers during the 1980s and the nearly universal problem with hepatitis C infection in patients who began transfusion therapy before the 1990s. A 1987 study found that 17% of patients with thalassemia major in one center in New York City were positive for HIV antibody.[140] The prevalence of hepatitis C infection among patients with thalassemia major is 12% to 91%, with a higher rate among older patients.[141,142] Improvements in donor screening and testing have markedly reduced the risk of transmission by transfusion of known viruses,[143] but patients with thalassemia, because of the frequency of their transfusions, remain at risk not only for viruses that are transmitted infrequently but also for new agents such as hepatitis A, babesiosis, and West Nile virus.[144] Hepatitis B vaccine, if not administered as part of the routine childhood immunization program, should be given to patients with thalassemia before transfusion therapy begins.[145] Hepatitis A vaccine should also be administered when age appropriate. The cytomegalovirus (CMV) status of patients who are potential candidates for stem cell transplantation should be ascertained prior to transfusion and every attempt should be made to provide them with CMV-negative blood products. Current studies of pathogen-inactivated RBC products hold forth the promise of a means for preventing transfusion-transmitted infections even when the donor's infection escapes detection or when new agents enter the blood supply.[146,147]

Progressive iron overload is the life-threatening complication of transfusion therapy that accounts for the most important long-term morbidity and mortality in patients with thalassemia major.

Chelation Therapy

The clinical effects of iron overload in patients with thalassemia major depend on the amount and the duration of excessive iron accumulation. Transfusion hemosiderosis is the major cause of late morbidity and mortality in patients with thalassemia major. Establishment of

therapeutic strategies to achieve iron balance should lead to improved survival. Various strategies to reduce the rate of transfusion iron loading have included modifying the pretransfusion hemoglobin level, adjusting the intervals between transfusions and splenectomy as well as with methods to enhance the rate of iron removal through chelation therapy. Historically, efforts were focused on identifying methods to enhance parenteral iron chelation by adjusting the frequency of daily use, the hours of administration, and the route of parenteral administration. These have optimized the use of iron chelation with deferoxamine (Desferal, DFO). More recently, efforts are focused on addressing the safety and efficacy of new U.S. Food and Drug Administration (FA) approved oral iron chelators, deferasirox (Exjade) and deferiprone (L1), combination use of parenteral and oral iron chelators, and new ways to assess iron excess by magnetic resonance imaging (MRI).

Each unit of packed RBCs contains approximately 200 to 250 mg of iron. Based on usual blood requirements in patients with thalassemia major, the rate of transfusional iron accumulation is approximately 0.30 to 0.60 mg/kg/day. The massive IE associated with the intermedia and major thalassemias leads to excessive gastrointestinal iron absorption that adds to the transfusional iron burden, although absorption is reduced when a hemoglobin level above 9 g/dL is maintained.[148,149] Humans have no physiologic mechanism to induce significant excretion of excess iron. Phlebotomy, the most efficient method of removing iron in other situations, is precluded in severely anemic patients with thalassemia owing to transfusion dependence. Phlebotomy may be only applicable in a very few select patients with thalassemia intermedia and constitutes an important part of the management of patients with thalassemia major who have successfully undergone stem cell transplantation (see box on Benefits of Iron Chelation Therapy).

A pharmacologic approach using specific iron-chelating agents remains the only strategy for removing excess iron in transfusion-dependent patients.

Several drugs with chelating properties have been synthesized or recovered from microorganisms. Many lack iron specificity or are inefficient; others cause significant toxicity. To chelate iron, the chelating agent must complex with all of the iron atom's six available coordination sites. Three general classes of iron chelators occur or have been synthesized: hexadentate (deferoxamine), bidentate (deferiprone), and tridentate (deferasirox). Only one hexadentate molecule is necessary to bind one atom of iron, but three molecules of a bidentate iron chelator bind one iron atom and two molecules of a tridentate chelator are required to bind one atom of iron.

Chelatable iron is thought to be derived from the intracellular "labile iron pool"[150,151] and from non–transferrin-bound plasma iron.[152,153]

Benefits of Iron Chelation Therapy

More than 30 years of experience using iron chelation therapy with deferoxamine in thalassemia major patients have demonstrated that:

1. Liver iron concentrations can be maintained at normal or mildly elevated levels.
2. Hepatic fibrosis is slowed or prevented.
3. The risk of iron-induced cardiac disease, including heart failure and serious arrhythmias, is markedly decreased.
4. Normal growth and sexual development are common but not universal.
5. Long-term survival is substantially improved. These benefits are directly related to compliance and generally require the prolonged administration of deferoxamine at least five times per week.
6. Long-term safety and efficacy studies of the oral iron chelators deferiprone and deferasirox are ongoing.

Deferoxamine

Deferoxamine mesylate is a naturally occurring hexadentate siderophore isolated from cultures of *Streptomyces pilosus* introduced in 1960. Deferoxamine has a high molecular weight of approximately 600 g/mol, is poorly absorbed by the gastrointestinal tract, and is rapidly removed from the plasma. It has a relatively short half-life of 8 to 10 minutes, which necessitates intravenous or subcutaneous parenteral administration. It is a hexadentate iron chelator that binds iron in a one-to-one complex. It is highly specific for iron and is associated with relatively low toxicity.[154] Deferoxamine enters cells; chelates iron; and appears in the serum and bile as the iron chelate product, ferroxamine.[155] Deferoxamine chelates iron released by the reticuloendothelial systems (RES) after the catabolism of senescent RBCs and is excreted in the urine.[156] Unbound deferoxamine is absorbed by the hepatic parenchymal cells and chelates iron from the intracellular pool which is excreted in bile. Approximately one-half to two-thirds of the iron excreted in response to deferoxamine is in the stool, with the remainder in the urine.[157] These proportions vary from patient to patient and at different levels of iron overload, dose of deferoxamine, and endogenous erythropoietic activity.[158]

Iron excretion after the administration of deferoxamine is proportional to body iron stores. To achieve negative iron balance, the chelating agent must cause the daily excretion of 0.3 to 0.6 mg/kg of iron. In the 1960s, deferoxamine was initially administered by daily intramuscular injections of 0.5 g, which led to reduced rates of hepatic iron accumulation and hepatic fibrosis in patients with thalassemia.[159,160] However, intramuscular injections proved to be too painful and were insufficient to achieve negative iron balance. In the mid-1970s, it was demonstrated that iron excretion with deferoxamine at 20 to 60 mg/kg/day was markedly enhanced and negative iron balance was attained by continuous, prolonged 24-hour intravenous or 8- to 12-hour subcutaneous infusions administered via a lightweight battery-operated or balloon-driven pump.[161,162] In addition, maintaining normal ascorbic acid levels optimizes iron excretion because it increases tissue iron turnover in the plasma.

Continuous, slow deferoxamine infusions allow for a longer exposure of the drug to the relatively small nontransferrin iron or labile iron pool that is in equilibrium with a nearly nonchelatable iron pool.[163]

A pump infuses an aqueous solution of deferoxamine through a small 27-gauge butterfly needle placed under the skin of the abdomen, thigh, or extremities. Most patients use the pump during sleep.[164] Bolus subcutaneous injections of deferoxamine used twice daily induce levels of urinary iron excretion comparable with subcutaneous infusions and may prove helpful as a respite from overnight infusions in some patients not adherent to prolonged infusions.[165,166] In patients who are poorly compliant with subcutaneous therapy, administration of deferoxamine in normal or higher doses can be accomplished intravenously by means of a deep line indwelling catheter, externalized venous catheter, or subcutaneous port. Continuous intravenous administration of deferoxamine is particularly useful for rapidly lowering the total iron burden and is used for reversal of cardiac morbidity (e.g., cardiac arrhythmias or left ventricular dysfunction). Complications of indwelling catheters, including infection and thrombosis rates, have been reported at 1.2 and 0.5 per 1000 catheter days, respectively, in patients treated over 1 to 5 years.

Prolonged infusions of deferoxamine achieve negative iron balance in most transfusion-dependent patients older than 4 or 5 years of age.[116,167-171] This approach to chelation therapy involves daily 8- to 12-hour subcutaneous infusions of 20 to 60 mg/kg of deferoxamine that should result in 20 to 50 mg/day of iron loss in the urine and stool.[116]

The optimal age for beginning parenteral or oral iron chelation therapy in patients with thalassemia has not been established with certainty. The surprisingly high liver iron concentrations that have been found in some patients with thalassemia within the first 2 to 3 years of transfusion therapy, occasionally accompanied by histologic finding of fibrosis, provided the rationale for the early initiation of deferoxamine iron chelation.[172,173] On the other hand, iron excretion

in response to deferoxamine is relatively low during the first few years of iron accumulation, and the pharmacokinetics and clearance of iron chelators in children is being further evaluated. Regular deferoxamine chelation therapy begun after the age of 3 to 5 years seems capable of removing previously stored iron and preventing iron-induced liver disease.[116] Data show that deferoxamine started by the age of 2 to 4 years forestalls significant iron overload; however, it also promotes elimination of excess iron in patients if started after significant transfusional iron burden has already developed.[174-184] Moreover, deferoxamine may adversely affect bone development and growth in some young patients and the effect of newer oral chelators on growth has yet to be addressed.[185-187] Some investigators have recommended the baseline and annual assessment of liver iron concentration of greater than 3 mg Fe/g dry weight as a guide for determining the appropriate time to begin iron chelation therapy[173] or a test infusion of deferoxamine to determine if mobilizable iron is present.[188] Others have based this decision on the number of transfusions administered to the patient, that is, approximately 10 to 25 units of blood and a serum ferritin level above 1000 ng/mL, a level that usually occurs after 1 to 2 years of transfusions.[189] Still others wait until the patient is older than 3 years of age, when significant iron excretion can be accomplished and patient cooperation is better[116,187] (see box on Assessment of Iron Stores).

The most common side effect of subcutaneous deferoxamine therapy is inflammation and induration at the site of infusion. Painful lumps may occur despite rotation of infusion sites, appropriate dilution of the drug, and proper placement of the needle. Some investigators have recommended the addition of small amounts of hydrocortisone to the infusion to prevent local reactions. Patients receiving aggressive chelation therapy with lower iron burdens may be more susceptible to toxicity. Neurosensory toxicity of deferoxamine is dose related and inversely correlated with body iron burden. Impairments of visual and auditory acuity are associated with high doses of deferoxamine relative to the iron load.[194] The ototoxicity is characterized by bilateral high-frequency hearing loss. The retinal toxicity is characterized by the loss of night and color vision, retinal atrophy, and cataract formation.[195] Patients receiving deferoxamine should undergo baseline and annual audiograms and ophthalmologic examinations. Deferoxamine should be discontinued if such abnormalities arise, with cautious reinitiation at lower doses when abnormalities improve or resolve. The risk of visual and auditory side effects can be minimized by adjusting the daily deferoxamine dose to the patients' serum ferritin level.[194] Impaired growth associated with growth plate deformities or metaphyseal rickets-like changes in the long bones and histologic evidence of cartilage dysplasia may occur in young children receiving deferoxamine.[185-187] Regular monitoring with plain radiographs of the extremities and vertebral column allows early detection of this complication and reduction in the dose of deferoxamine or temporary interruption of chelation therapy.

Other, less common complications of deferoxamine include anaphylaxis, hypotension, allergic reactions, acute pulmonary disease, impairment of renal function, and infection.[196-202] Severe allergic reactions are rare, and desensitization has been achieved successfully in some patients.[198,199] Acute pulmonary disease and renal failure have occurred in a few patients receiving unusually high doses of deferoxamine by intravenous infusion.[200] The mechanism of this toxicity is unclear. One of the most serious complications of deferoxamine is an increased risk of infection with *Yersinia* and mucormycosis, which uses the deferoxamine iron chelate as a siderophore, whereby enhancing their growth and presenting as colitis, abdominal abscess, or sepsis.[201,202] The safety of deferoxamine during pregnancy has been inferred from case reports rather than formal studies. A summary of these case reports identified 11 women who received deferoxamine beginning in the first trimester and 33 women who used the chelator beginning in the second or third trimester.[202] None of the infants showed evidence of drug-related toxicity.[203]

Regular chelation with deferoxamine has proven remarkably effective in reducing the transfusional iron burden of thalassemia patients. Increasing evidence indicates that endocrine dysfunction is improved and cardiac disease is delayed or prevented with standard deferoxamine regimens.[204] Cardiac arrhythmias and congestive heart failure have reversed in some patients with standard or aggressive deferoxamine regimens, and life expectancy is significantly prolonged.[205-207] Intense 24-hour intravenous deferoxamine regimens of no more than 15 mg/kg/hr have been reported to reverse early

Assessment of Iron Stores

Because excess transfusional iron cannot be actively excreted it is deposited in the macrophages of the RES. When the RES is overwhelmed, iron spills over into parenchymal tissue, generating free radical damage with cellular membrane lipid peroxidation and leading to end-organ dysfunction, especially of the liver, endocrine system, and myocardium.

The best strategy for monitoring iron accumulation in patients with thalassemia remains controversial. Multiple approaches should be considered to assess iron stores, including transfusion requirements, ongoing transfusion burdens, serum ferritin, and liver and cardiac iron concentration. Before chelation therapy is begun, careful recording of transfusion volumes provides an accurate assessment of iron loading. Each milliliter of RBCs contains approximately 1.1 mg of iron. Therefore, each unit of blood contains approximately 200 mg of iron. The total transfusional iron intake can be calculated from the transfusion record and should be as useful in determining the need to begin chelation therapy as indirect or direct measures of body iron stores. Chelation therapy is initiated after approximately 10 to 25 units of blood have been transfused, serum ferritin levels are above 1000 mg/mL, and liver iron concentration is greater than 3 mg Fe/g dry weight. However, when chelation therapy has been initiated, iron is going out as well as coming in. Under these circumstances, regular assessment of iron stores is needed to determine the severity of iron overload and to achieve an optimal treatment program.

Measurement of liver iron concentration by biopsy provides a direct assessment of tissue iron loading and reflects total body iron stores but liver biopsy requires a skilled technician, at least 1 mg of tissue at least 2.5 cm in length with five portal tracts and has the risk of hemorrhage. MRI changes in R2 reflects liver iron concentration comparable to that on liver biopsy. The use of MRI to estimate hepatic and cardiac iron in patients with transfusional siderosis has largely replaced liver biopsy for liver iron concentration quantification at the start of chelation therapy and with annual assessments. Future MRI use may involve the quantification of iron concentration of endocrine glands to predict or monitor dysfunction.[190-192] Levels between 3 and 7 mg Fe/g dry weight appear to be associated with minimal toxicity. Levels greater than 15 mg Fe/g dry weight are associated with an increased risk of heart disease. Recent experience with cardiac magnetic resonance imaging suggests that changes in T2* reflect levels of iron in the heart and may predict adverse changes in cardiac function.

Serum ferritin levels are safe, inexpensive, and readily available, and serial measurements are predictive both of critical complications such as iron-induced heart disease and of adverse effects of chelation therapy such as impairment of vision and hearing. However, single ferritin levels may correlate poorly with liver iron concentration because it is an acute phase reactant and may be influenced by inflammation, vitamin C deficiency, hepatitis, and other infectious states. Transferrin saturation is not very useful in evaluating the severity of iron overload in patients with thalassemia because the massive IE usually results in a transferrin saturation greater than 60% even in the absence of iron overload.[193]

Noninvasive hepatic MRI of liver iron by R2 changes correlates with liver iron concentration by biopsy but cannot be used in patients with pacemakers or those who are claustrophobic.

cardiac hemosiderosis, but even more conventional doses of 50 mg/kg/day have improved left ventricular ejection fractions and prevented death in some patients.[208,209]

Before subcutaneous deferoxamine therapy, estimated survival was approximately 16 to 17 years of age, with rare patients surviving into their mid-20s.[116,206,210,211] Since regular subcutaneous deferoxamine regimens have been in use, life expectancy has extended into the fourth decade of life.[212-214] The increasing widespread use of deferoxamine has steadily increased survival probabilities worldwide.[213,214] However, long-term European studies have demonstrated that improved survival times are clearly related to the degree of compliance with chelation regimens and are associated with lower serum ferritin levels (<1000 mg/mL).[215] Deferoxamine chelation regimens are clearly cumbersome, inconvenient, and costly. More tolerable approaches are required, and investigations for alternative oral iron-chelating agents have been ongoing and recently more successful.

Although the prevalence of endocrine disturbances, for example, glucose intolerance and diabetes have reduced since the regular use of subcutaneous deferoxamine,[109,112,204] they persist, especially in those in whom deferoxamine was initiated late in their first decade of life.[179] Growth hormone deficiency, hypothyroidism, hypoparathyroidism, vitamin D deficiency, diabetes, and osteoporosis are still observed, and there is little evidence that deferoxamine can reverse established endocrine dysfunctions. The North American Thalassemia Clinical Research Network Registry reported that 96% of thalassemia patients with median age of 20 years were free of hypoparathyroidism, 91% were free of thyroid disease, 90% were free of diabetes mellitus, and overall 62% were free of any endocrinopathy.[216]

It remains to be determined if starting chelation at a very young age or more easily administered use of oral iron chelation will diminish the endocrine morbidities and further prolong survival associated with iron overload. Direct and indirect measures of iron stores reflect the progress of chelation therapy and help determine appropriate changes in the dose or frequency of chelator use. The serum ferritin level generally declines during regular chelation therapy and may decline rapidly in the first year of treatment in patients with very large iron stores.[167,169] Serum ferritin levels measured over time with use of deferoxamine have predicted the risk of iron-induced heart disease in patients with thalassemia major, and the ratio of the dose of deferoxamine to the ferritin level has identified patients at risk for auditory and visual complications of chelation therapy.[194,207] Although easy to obtain and relatively inexpensive, the serum ferritin level may be increased in the presence of inflammation and may be decreased when iron overload is accompanied by vitamin C deficiency.[217] For these and other reasons, serum ferritin levels frequently correlate poorly with liver iron concentrations, and clinicians and patients may have a false sense of security when the ferritin level is below 2000 μg/L. Some studies using deferoxamine suggest ferritin levels lower than 1000 μg/L are associated with better survival times and less cardiac disease as well as hepatic histology and pathology.[215,218,219]

Liver biopsy with biochemical measurement of iron concentration provides a more direct assessment of iron overload, and some investigators recommend such testing yearly. Hepatic iron levels of 15 mg/g dry weight have been associated with a greater risk of iron-induced heart disease.[174] The meaning of lower hepatic iron levels has generally been inferred from experience with primary hemochromatosis.[220] Further studies are needed to determine the clinical usefulness of liver iron concentration in the overall management of thalassemia. Noninvasive techniques using magnetic susceptometry and MRI for assessing tissue iron offer the possibility of serial measurements without substantial risk to the patient. The noninvasive measurement of iron in the liver, heart, and other target organs is in development. Measurements of liver iron concentration by magnetic susceptometry using a superconducting quantum interference device (SQUID) correlate well with biochemical measurements of tissue iron.[221,222] At present, measurement of tissue iron by SQUID is limited to the liver, and the instruments are available in only two sites in the United States and two sites in Europe. The ability to use MRI to measure iron stores would dramatically extend the availability of noninvasive tissue iron measurements. Investigators have reported success using proton transverse relaxation rates (R2) with spin-echo imaging, signal intensity ratios, and gradient-echo T2* to assess liver iron concentration.[223-227] The latter two techniques also yield information that appears and to reflect cardiac iron loading. Direct comparisons with hepatic tissue samples demonstrate significant correlations ($r = 0.97$ vs. 0.95) with biopsy-measured liver iron concentrations in two separate studies.[224,226-230] These noninvasive technologies to measure liver, cardiac, and other tissue iron concentration may prove useful in the future to refine therapeutic strategies. Current needs include the further refinement of MRI techniques and a better understanding of the relationship between liver iron, iron in other organs (particularly the heart), and clinical complications of iron overload.

A relationship between iron overload and ascorbic acid depletion, first suggested by the epidemiology of scurvy among the Bantu, exists in thalassemia major.[99,217] For thalassemia patients with low levels of ascorbic acid, daily supplementation with 100 to 200 mg of this vitamin increases urinary iron excretion in response to deferoxamine by approximately twofold.[100,163] Ascorbic acid may retard the conversion of ferritin to hemosiderin and therefore allow more iron to remain in the chelatable form.[231,232] However, it can also enhance iron-mediated peroxidation of membrane lipids[233,234] as well as membrane damage in cultured myocardial cells.[235] Cardiac toxicity manifested as arrhythmias and decreased ventricular contractility has been attributed to vitamin C therapy.[236] Ascorbic acid should be used only while deferoxamine is being administered and only in patients who are ascorbate depleted.

Chelation therapy with deferoxamine is expensive and cumbersome because of the need for daily or nightly subcutaneous infusions. Regular infusions require a great deal of dedication and persistence from the patient and family. Noncompliance is common, particularly in the teenage and young adult years, and failure to follow prescribed treatment regimens is the major cause of mortality in patients with thalassemia major.[215] The cost and complexity of deferoxamine administration prevents its availability worldwide, especially in developing countries. The search for a less expensive iron chelator that can be more easily orally administered led to the identification of compounds such as deferiprone and deferasirox.

Deferiprone

One such oral agent is 1,2-dimethyl-3-hydroxypyrid-4-one (L1, deferiprone), a synthetic compound with a low molecular weight of approximately 200 g/mol. It is an orally active bidentate iron chelator that requires three molecules to bind one iron atom. Deferiprone is absorbed by the gastrointestinal tract and has a plasma half-life of approximately 90 minutes (2-3 hours). Chelated iron is excreted predominantly in the urine (90%) and far less in the stool (10%). It was synthesized in the late 1980s and was first tested in uncontrolled clinical trials at the Royal Free Hospital in London, hence the eponym L1.[237,238] Subsequent clinical efficacy studies appeared initially encouraging,[239-241] but its long-term efficacy and safety have not been totally established.[240,242-246] Retrospective studies have shown reduced cardiac morbidity and mortality and lower cardiac iron deposition in patients treated with deferiprone compared with deferoxamine.[247,248] A large observational study demonstrated improvement in cardiac iron deposition with deferiprone treatment.[249] Unfortunately, deferiprone was not subjected to phase III studies in which its safety and efficacy were directly compared with those of deferoxamine. Nonetheless, at doses of 75 mg/kg/day, deferiprone administered in three divided doses with meals reduces or maintains iron stores, thereby achieving negative iron balance or iron balance in many regularly transfused patients for the most part, particularly those with more severe transfusional iron overload.[239,240,242-246,250,251] However, some patients remain in positive iron balance and continue to accumulate iron during long-term therapy with this dose of deferiprone.[240,244,252] Some studies have shown the reduction of serum ferritin levels and liver iron concentration in most, but not all, patients with transfusional iron overload.[247] Regimens using higher doses up to 100 mg/kg/day of deferiprone may be more effective.[248] Combination

regimens with deferoxamine may also reduce iron stores or prove effective in restoring negative iron balance in some of these patients.[253-255] Enhanced urine and stool iron excretion in thalassemia patients using both deferoxamine and deferiprone have suggested an additive effect postulated by the shuttle hypothesis, that is, deferiprone may chelate intracellular labile iron and shuttle it to deferoxamine.[256] Some studies have also suggested that deferiprone alone or in combination with deferoxamine may be more effective than deferoxamine in removing iron from the heart, improving cardiac function, and preventing iron-induced cardiac disease.[230,251,257-260] Schedules for combination therapy vary but have usually included 5 to 7 days of deferiprone and 2 days of subcutaneous deferoxamine weekly. Intensive combined chelation therapy has been reported to reverse both cardiac and endocrine complications of thalassemia major.[261]

Side effects of deferiprone include gastrointestinal complaints, mostly nausea and some vomiting that occur in approximately 33% of patients and usually resolve without specific intervention. Arthropathy with arthralgias and some joint effusions occur in approximately 15% of patients. The incidence of joint symptoms varies widely among various studies but may be severe enough to require reduction or interruption of chelation therapy. Abnormal liver function tests may occur gradually or suddenly and in the absence of other causes of hepatic dysfunction. These elevations may return to baseline values with the interruption of deferiprone followed by reinitiation beginning with lower doses and close monitoring of liver function tests. Progressive liver disease attributed to deferiprone has not been reported, and concerns about drug-induced hepatic fibrosis have not been substantiated by subsequent studies.[240,243,262,263] However, in vitro evidence shows that deferiprone may potentiate oxidative DNA damage in iron-loaded liver cells that could occur when the concentration of iron is low relative to the iron chelator (Fig. 38-8).[264] Agranulocytosis occurs in 1% of patients and, although rare, remains the principal concern for patients receiving deferiprone. Milder neutropenia is more common and occurs in approximately 8% of patients. Severely depressed neutrophil counts represent a significant risk of sepsis and hospitalizations, and in some cases, administration of granulocyte colony-stimulating factor (G-CSF) is required. Some reported deaths have been related to deferiprone-induced agranulocytosis or neutropenia. Regular weekly monitoring of blood counts during deferiprone therapy is essential to detect the rare but important deferiprone-induced complications of neutropenia and agranulocytosis.[244-246,265]

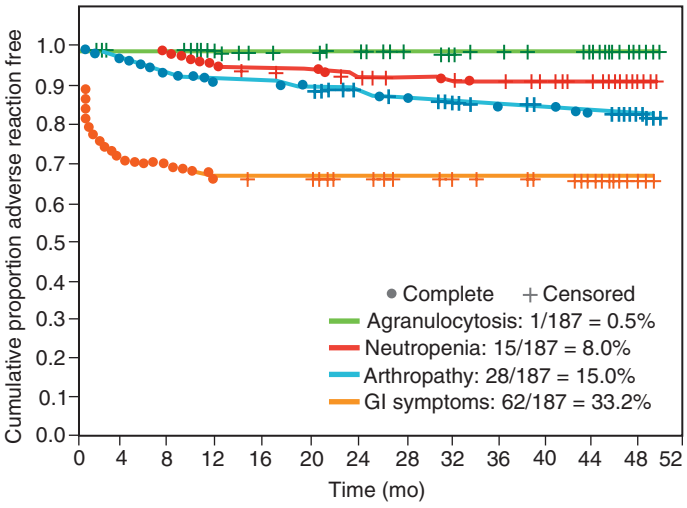

Figure 38-8 KAPLAN-MEIER CURVES SHOWING THE TIME TO FIRST OCCURRENCE OF IMPORTANT ADVERSE EVENTS IN PATIENTS TREATED WITH DEFERIPRONE. The only case of agranulocytosis occurred in the first year, and gastrointestinal complaints were very uncommon after the first year. Neutropenia and joint problems occurred throughout the 4-year study period but were more common in the first year than in each of the subsequent years. *(Adapted from Cohen AR, Galanello R, Piga A, et al: Safety and effectiveness of long-term therapy with the oral iron chelator deferiprone.* Blood *102:1583, 2003.)*

Several clinical studies of deferiprone speak to its relative safety and utility demonstrated by a decline in serum ferritin levels in the majority of patients.[230,243-246,250,251,257,258,260] Retrospective studies have suggested that deferiprone might be more effective than deferoxamine in chelating cardiac iron. Two multicenter studies have further supported the theory that combination therapy increases total iron excretion and selectively reduces organ iron burden.[258,260] Longitudinal clinical studies using innovative MRI technology to measure cardiac (T2*) and liver iron concentration have demonstrated higher estimated liver iron concentration but lower myocardial iron concentration in deferiprone-treated thalassemia patients compared with those treated with deferoxamine.[257] In another study, thalassemia patients using deferiprone did not experience any cardiac events or any cardiac-related deaths compared with thalassemia patients taking deferoxamine who experienced both cardiac events and some deaths.[258] In another 1-year prospective trial of cardiac iron and function, thalassemia patients treated with deferiprone or deferoxamine had improved myocardial T2* values but more so in the deferiprone-treated group, who also showed a greater improvement in left ventricular ejection fraction. Liver iron concentration fell significantly in the deferoxamine-treated patients but not in the patients receiving deferiprone. A prospective randomized study comparing the combination of deferiprone at 75 mg/kg/day and deferoxamine at 40 to 50 mg/kg/day with deferoxamine alone demonstrated that the combination therapy more rapidly reduced hepatic and cardiac iron stores than deferoxamine alone.[266] Further prospective studies are warranted, especially with the combination of deferiprone with deferoxamine. Deferiprone may play a role in shuttling iron from within intracellular pools and enhance the available iron pool to bind with deferoxamine.[243,267-269] Deferiprone continues to be tested in clinical trials alone and in combination with deferoxamine to address its impact on cardiac function.[260] The safety profile of deferiprone has been largely defined by single-center studies, multicenter trials, and postmarketing surveillance largely in European and Asian continents. Deferiprone is currently licensed in both Europe and the United States of America as of 2011 as alternative iron chelation therapy for those who are unable to be successfully treated with deferoxamine.

Deferasirox

Deferasirox (ICL670, ExJade) is an orally active iron chelator that was identified by computer technology at Novartis Pharmaceuticals in the 1990s. It is a tridentate compound known as 4-(3,5-bis[2-hydroxyphenyl]-1*H*-1,2,4-triazol-1-yl)-benzoic acid,[270] wherein two molecules of deferasirox are required to bind one atom of iron. It has a high affinity for iron and a much lower affinity for copper and zinc. Deferasirox is orally bioavailable with a low molecular weight of 373 g/mol and is absorbed by the gastrointestinal tract. It has a dose-dependent plasma half-life of 12 to 18 hours that allows for once-daily oral administration after fasting on an empty stomach.[271] Deferasirox is given as a suspension in water or apple or orange juice.[272] Iron excretion in response to deferasirox is largely in the stool (90%) and far less in the urine (10%).[272] The pharmacodynamic effects of deferasirox tested in a phase I clinical iron balance metabolic study measuring stool and urine iron excretion demonstrated increasing iron excretion at doses of 10, 20, and 40 mg/kg/day, which induced a mean net iron excretion (0.119, 0.329, and 0.445 mg Fe/kg/day, respectively) within the clinically relevant range of the rate of transfusion iron loading for most patients.

The phase III worldwide multicenter open-label randomized active comparator control study of deferasirox compared with deferoxamine was conducted in 65 sites with 586 regularly transfused patients 2 years or more of age with β-thalassemia. Results indicated that chronic daily use of deferasirox, via a single oral dose of 20 to 30 mg/kg/day, induced decreases in liver iron concentration by biopsy comparable to that achieved with deferoxamine. Patients with liver iron concentrations greater than 7 mg/g dry weight receiving deferasirox at 20 to 30 mg/kg/day had a mean decrease of 5.3 mg/g

dry weight that did not differ significantly from a mean decrease of 4.3 mg/g dry weight in patients receiving 35 mg/kg/day or more deferoxamine. Changes in serum ferritin were dose dependent in both treatments, paralleling trends in liver iron content.[273] Doses of 5 and 10 mg/kg/day of deferasirox were unlikely to achieve negative iron balance and did not maintain or reduce absolute liver iron concentration and serum ferritin levels increased at these lower doses. The rate of transfusional iron loading may also influence the effectiveness of deferasirox in controlling liver iron concentration.[274] Using a dose of 20 to 30 mg/kg/day of Deferasirox to reduce liver iron concentration has been demonstrated in several additional studies.[274-276] Deferasirox was given orphan drug status and was approved by the FDA in 2005 in the United States.

Higher doses of Deferasirox at 30 to 50 mg/kg/day have been demonstrated to significantly improve cardiac T2* iron deposition over 2 years of treatment in two groups of thalassemia patients with normal ventricular function but with either moderate to mild siderosis (T2* = 10 to <20 ms) or severe (T2* >5 to <10 ms) cardiac siderosis.[277] Failure of T2* cardiac siderosis to respond to deferasirox has been predicted by higher baseline liver iron concentrations and ferritin levels.[278] Deferasirox has also been shown to prevent cardiac iron accumulation in thalassemia patients without evidence of cardiac siderosis as well as improvement in left ventricular function.[279]

Deferasirox was generally well tolerated in these clinical trials. Mild gastrointestinal complaints and skin rashes were the most common adverse events. Discontinuation of deferasirox was rarely required, but abdominal discomfort occurred in 14% of patients, 12% with diarrhea, 10% nausea, and 9% vomiting. Mild increases in serum creatinine occurred in 38% of patients, and a small number exceeded the upper limits of normal; intermittent proteinuria was also observed in 19% of patients. Duplicate serum creatinine level should be assessed before initiating therapy. Close monthly monitoring of serum creatinine needs to be maintained because of nephropathy in animal studies and cases of acute renal failure that were reported after postmarketing use of deferasirox. Severe renal complications may occur in patients with preexisting renal disease. Dose reduction, interruption, or discontinuation should be considered for elevations in serum creatinine. Elevations in serum transaminases also occurred in a small number of patients (6%). Rare reports of fulminant hepatic liver failure have resulted in the recommendation to obtain liver function tests every 2 weeks for 1 month after starting therapy and then monthly thereafter with interruptions or discontinuations of deferasirox if unexplained or progressive transaminase increases occur. Skin rashes also occurred in 15% of patients usually within the first 2 weeks of treatment. The maculopapular eruptions often resolved spontaneously, but severe rashes may require interruption of deferasirox with antihistamine support and possible steroid administration after which deferasirox may be reintroduced at a lower dose with gradual dose escalation. Minimal (<1%) auditory and ophthalmologic toxicity occurred in the preliminary 1-year safety and efficacy trial. No agranulocytosis was observed in thalassemia subjects during the 1-year primary efficacy trial. Reports of pancytopenia have occurred in postmarketing reports, but mostly in patients with preexisting hematologic disorders such as myelodysplastic syndromes (MDS) that are frequently associated with BM failure.

Future Iron Chelation Research Strategies

Other approaches to improved chelation therapy have looked to both oral and parenteral therapy. The compound N, n'-Bis-(2-Hydroxybenzyl)ethylenediamine-N, n'-Dipropionic Acid (HBED), originally developed as a potential oral agent, has been shown in primate studies to be more effective when administered as a subcutaneous injection than deferoxamine administered by subcutaneous infusion.[280] The attachment of deferoxamine to a backbone of starch (S-DFO) extends the circulation time of the chelator, and early studies suggest that this novel form of deferoxamine may reduce the frequency of infusions required to achieve negative iron balance.[281] Another promising oral desferithiocin derivative, FBS0701, a member of the desazadesferrithiocin class of siderophore-related tridentate chelators, has been modified to limit nephrotoxicity and is entering phase II studies.[282]

Specific Complications and Their Management

Skeletal Changes

Skeletal abnormalities (Fig. 38-9) are less common in patients receiving regular RBC transfusions but may still occur as a result of partially unchecked IE and expansion of the erythroid BM.[283] These cause widening of the BM space and thinning of the cortex, with consequent osteoporosis.[284,285] Changes in the skull and facial bones, including expansion of the frontal bone with prominent frontal bossing, may occur before the initiation of transfusion therapy. Radiographs reveal the diploic spaces to be widened. At first, the skull has a granular appearance, but later perpendicular bony trabeculae appear, giving the classic "hair on end" or "crewcut" appearance. Marked overgrowth of the maxilla results in severe malocclusion, jumbling of the upper incisors, and prominence of the molar eminences.[286] These bone changes produce the classic facies. Additional skeletal changes are observed in the metacarpals, metatarsals, and phalanges, where expanded medullary cavities produce a rectangular and then a convex shape (see Fig. 38-9). Irregular fusion of the epiphyses of the proximal humerus results in characteristic shortening of the upper arms.[287,288] Marked osteoporosis and cortical thinning may predispose to pathologic fractures of the extremities and compression fractures of the vertebrae (Fig. 38-10).

Several abnormalities in the ribs may occur, including notching and osteolytic lesions.[283,289] The ribs become very wide, especially at the points of their attachment to the vertebral column. BM masses may extrude from these sites, creating the appearance of paravertebral masses and compressing the spinal cord.[290] Although bone deformities and extramedullary hematopoiesis are uncommon in properly transfused patients with β-thalassemia major, it is frequently observed in patients with thalassemia intermedia whose BM is not suppressed by regular transfusions (see the section Thalassemia Intermedia).

The character and degree of the bone lesions change significantly with age. In older children, the bone lesions regress in the more distal portions of the skeleton (hands, arms, and legs), a feature correlating with the normal developmental replacement of red BM by fatty BM. The characteristic changes of the hands and other peripheral areas are thus diminished and may disappear in later life.[109,291] However, in the skull, spine, and pelvis (which are sites of active, persistent erythropoiesis), the radiographic changes become more conspicuous.[129]

Growth and Endocrine Status

Growth retardation, including skeletal and dental deformities,[292] was common even in young children until the use of hypertransfusion regimens restored relatively normal growth during the first decade. Without iron chelation therapy, the adolescent growth spurt is often delayed or absent; most patients, even those well maintained by transfusion, may not attain normal stature, partly because of iron-induced damage to the hypothalamic–pituitary axis.[90,293,294] Menarche is frequently delayed. Breast development may be poor, and many female patients have primary or secondary amenorrhea. Boys are frequently immature, with sparse facial and body hair. Although spermatogenesis may be normal, libido is often decreased. A multicenter study of 250 adolescent patients in northern Italy showed that despite hypertransfusion and 7 to 10 years of deferoxamine iron chelation therapy, two-thirds of male patients and one-third of female patients older than 14 years of age were 2 standard deviations or more below the mean for height.[295] Many adolescents between 12 and 18 years of age lacked any secondary sexual changes of puberty. However, the mean serum ferritin level in the entire group was 3500 ng/mL, indicating persistence of a high level of excess iron burden in most of this group.

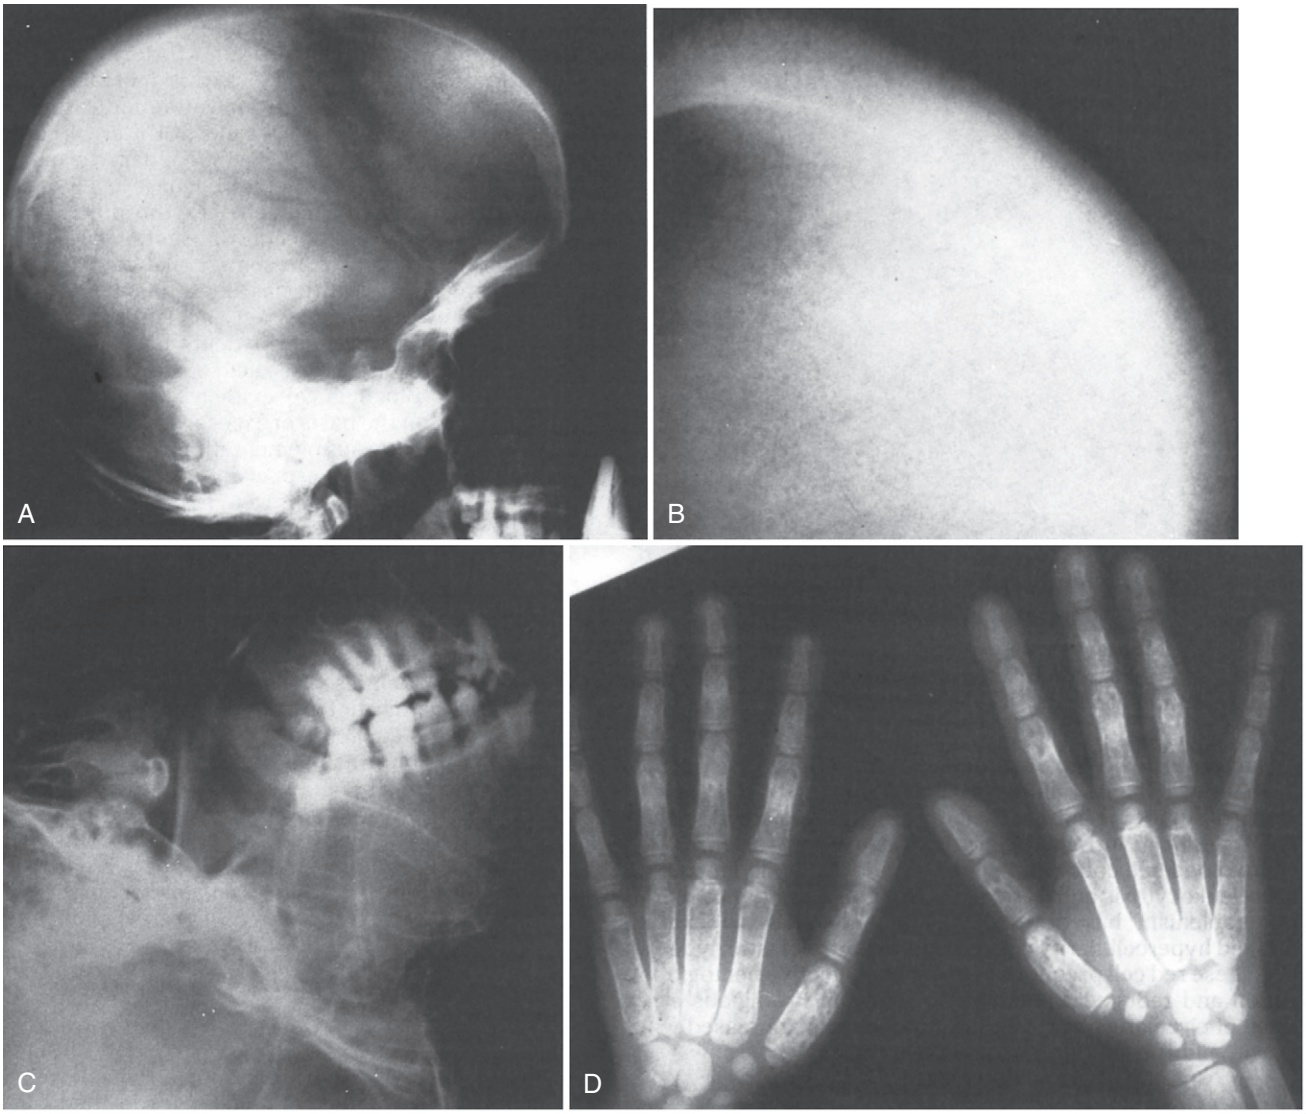

Figure 38-9 BONY ABNORMALITIES IN A PATIENT WITH SEVERE β-THALASSEMIA. **A** and **B**, "Hair-on-end" appearance of the skull, especially obvious in the close-up view shown in part **B**. **C**, Distortion of the maxillary bones, as well as poor development of the sinus cavities caused by opaque masses of extramedullary erythropoiesis. **D**, Squaring and convexity abnormalities of the hands. *(From Pearson HA, Benz EJ Jr: Thalassemia syndromes. In Miller DR, Baehner RL, McMillan CW, editors:* Smith's blood diseases of infancy and childhood*, ed 5, St. Louis, 1984, CV Mosby, p 439.)*

Regular chelation therapy started early in the first decade of life frequently allows a normal onset of puberty and development of secondary sexual changes.[296] Administration of recombinant human growth hormone in conventional doses increases height velocity in patients with growth hormone deficiency.[297,298] Normal or higher doses of recombinant human growth hormone increase growth velocity in patients with normal growth hormone reserve but low levels of insulin-like growth factor I.[299,300] For patients with a functional hypothalamic–pituitary axis, treatment with gonadotropin-releasing hormone may induce pubertal changes.[301] In others, administration of sex steroids is necessary to induce secondary sexual characteristics.

More than 100 pregnancies either have been achieved spontaneously in patients with normal menstrual function or have been induced in patients with primary or secondary amenorrhea.[302-307] Transfusion requirements frequently increase during pregnancy, especially during the third trimester.[302] Diminished ventricular contractility during pregnancy and the death from heart disease of at least one mother within 1 year of delivery argue strongly for the careful consideration of the overall clinical condition and degree of iron loading before planning a pregnancy.[305,308] The safety of chelation therapy

during pregnancy is discussed earlier. At least one successful pregnancy has occurred in a woman with thalassemia after BMT that included ablative therapy with busulfan and cyclophosphamide.[309]

Abnormal carbohydrate metabolism is common in older patients with thalassemia major. Prepubertal children usually have normal glucose metabolism, but pubertal patients exhibit impaired responses to glucose load. Higher than normal insulin levels despite normal glucose levels are also encountered during puberty.[310] The defect in these patients appears to be related to insulin resistance, with insulin deficiency developing later in the progression to diabetes. Rates of diabetes are reported close to 6% to 8%.[214] Diabetes occurs more frequently in patients with hepatitis C and hepatic dysfunction.[311-313] Oral hypoglycemic agents have been used to regulate hyperglycemia and may reduce the rate of further deterioration of glucose metabolism.[314]

Laboratory findings of hypothyroidism and hypoparathyroidism are present in approximately 14% of patients with thalassemia major.[315-319] Clinical findings associated with these deficiencies are uncommon.[320]

Low Bone Mass

With improved survival in patients with thalassemia major, the problem of osteoporosis has assumed greater importance. The widespread prevalence of osteoporosis in patients with thalassemia major was first observed across all ages in 1995.[285] Subsequently, others reported a high frequency of abnormal *Z* scores in pediatric, adolescent, and adult patients. Abnormal bone mineral density has been reported in pediatric and adolescent patients with thalassemia major.[321-323] The Thalassemia Clinical Research Network has identified the overall fracture prevalence of 12% in a contemporary sample of 702 patients with α- and β-thalassemia. The fractures occurred more frequently in thalassemia major (17%) and intermedia (12%) compared with β-E (7%) and α-thalassemia (2%). Facture prevalence increased with age and with sex hormone replacement therapy.[324] More recently an observational study by the Thalassemia Clinical Research Network has demonstrated a high prevalence of low bone mass across all the thalassemia syndromes, including β-thalassemia major, intermedia, β-E, hemoglobin H, H-Constant Spring, and homozygous α-thalassemia, which progresses with aging. Low bone mass is associated with high prevalence of fractures, hypogonadism, and increased bone turnover.[324,325] Bone resorption is usually increased, and new bone formation is decreased.[326] Treatment with some, but not all, bisphosphonates improves bone mineral density.[327-330] Vitamin D and calcium supplementation with age-appropriate hormone replacement therapy are important preventive measures, although low bone mass may still occur in treated patients. Gonadal steroid replacement of hypogonadal patients has been shown to improve bone mass in some studies.[325,331]

Liver and Gallbladder

Hepatomegaly occurring before the initiation of transfusion therapy in severely affected patients is primarily a consequence of extramedullary hematopoiesis. With the amelioration of the anemia, the liver diminishes in size. However, as transfusion therapy continues, iron accumulation provides a new reason for hepatomegaly and resultant liver injury. Iron deposition, first present in the Kupffer cells, ultimately engorges the parenchymal cells, resulting in an appearance that is indistinguishable from that of idiopathic hemochromatosis.[332-334] The hepatocellular injury of iron overload may be attributable to the liberation of hydrolases resulting from initiation by the ferrous form of iron and peroxidative damage of lysosomal membrane lipids.[335] Fibrosis is usually followed by cirrhosis and an increased risk of hepatocellular carcinoma. The risk of liver damage and the rate of progression may be increased by the concomitant presence of excessive iron with viral hepatitis. The concentration of liver iron that constitutes a threshold for liver damage in patients with thalassemia is similar to that found in patients with hereditary hemochromatosis. In contrast to hereditary hemochromatosis, however, death from liver failure or liver cancer is much less common than death from cardiac failure in patients with thalassemia.[213]

Regular chelation therapy is the key to maintaining normal or near-normal hepatic iron concentrations and preventing iron-induced hepatic fibrosis and cirrhosis. Treatment with deferoxamine slows or prevents iron-induced liver damage and may reduce the severity of preexisting fibrosis in some cases.[159,179,336] Results of treatment of hepatitis C in patients with thalassemia major are similar to those found in other patients. Sustained viral responses occur in 28% to 40% of patients treated with interferon alone and, in two smaller series, 46% to 72% of patients treated with interferon and ribavirin.[337-341] Transfusion requirements increase by 30% to 40% in patients treated with ribavirin as a result of drug-induced hemolysis.[338,340,341] Lower levels of viral RNA and non-1 genotypes are associated with better responses. Higher iron levels adversely affect the response to antiviral therapy in some studies but not in others.[337,339,342] The Thalassemia Clinical Research Network studied the use of pegylated interferon and ribavirin in 16 thalassemia patients. Fifty percent genotype 1 patients had sustained viral response as well as 25% of genotype 2 and 3 patients; median transfusion requirements increased by 44% after 24 weeks of treatment, and liver iron concentration increase of more than 5 mg/g dry weight occurred in 29% of patients, but overall liver iron concentration remained stable over the course of the study. In addition, neutropenia occurred in 52% of patients.[341] Interferon therapy in patients with hepatitis C who have previously undergone BMT is as effective and safe as in nontransplanted patients.[343]

Pigmentary gallstones caused by high levels of bilirubin production are found in an increasing number of patients older than 4 years old. Two-thirds of patients have multiple calcified bilirubinate calculi after the age of 15 years.[344] Gallbladder surgery is not usually indicated unless biliary colic or obstructive jaundice has occurred.

Heart

Cardiac abnormalities are important causes of morbidity and mortality in patients with thalassemia major. Cardiac enlargement secondary to anemia is almost always present in untransfused children (see Fig. 38-9). Before the availability of chelation therapy, myocardial hemosiderosis and serious iron-induced cardiac diseases were inevitable during the second decade. These problems still occur often in older patients with thalassemia who are poorly compliant with chelation therapy, and heart disease, usually in the form of cardiac failure or serious arrhythmias, remains the most common cause of death in patients with thalassemia major.[213,215]

Left-sided heart failure predominates in patients with thalassemia major and is characterized by dyspnea and orthopnea.[345] Right-sided heart failure is less common but may be the presenting cardiac finding in older patients with more severe iron overload. Symptoms include hepatic pain, abdominal discomfort, and peripheral edema. Acute myocarditis, which occurs in approximately 5% of patients with thalassemia, is frequently followed by acute or chronic heart failure.[346]

Early electrocardiographic abnormalities include a prolonged P–R interval, first-degree heart block, and premature atrial contractions. Later, ST-segment depression and ventricular ectopic beats constitute ominous indicators of myocardial damage. Periodic evaluation of cardiac function is essential to detect iron-induced heart disease and to identify patients who will benefit from more intensive chelation therapy (see later discussion). Unfortunately, by the time cardiac results of studies such as echocardiography and 24-hour rhythm monitoring become abnormal, clinical heart disease is imminent. Whether assessment of cardiac iron by MRI using T2* or other measures can better anticipate the development of clinical heart disease is currently under investigation.

In the absence of intensified chelation therapy, ventricular dysfunction progresses rapidly to chronic refractory congestive heart failure, and arrhythmias become increasingly difficult to control. In the past, death usually occurred within 1 year of onset of heart failure.

More recent data demonstrate a survival rate of 48% at 5 years.[345] Survival is notably poorer in patients with heart failure after myocarditis or with heart failure accompanied by arrhythmias.[346]

In addition to standard therapy for heart failure and arrhythmias, including angiotensin-converting enzyme inhibitors, β-blockers, diuretics, and antiarrhythmic agents, the pretransfusion hemoglobin level should be maintained between 10 and 12 g/dL. The volume of transfused RBCs should be reduced as needed to prevent acute fluid overload. Because the iron-overloaded myocardium has little capacity to improve its performance unless excess iron is removed, intensive chelation therapy is a critical part of the management of heart disease in patients with thalassemia. Several studies have shown that heart failure can be reversed in many patients with the use of continuous treatment with deferoxamine.[205,347,348] The benefits of this approach may derive from the reduction in cardiac iron stores, the prevention of acute toxicity from non–transferrin-bound iron, or a combination of these two mechanisms. Recent data suggest that deferiprone may be more effective than deferoxamine in reducing the cardiac iron load and treating iron-induced cardiac disease, perhaps because of deferiprone's ability to enter cardiac cells more rapidly than deferoxamine.[230,257] Different iron chelators seem to have different accessibility to hepatic and extrahepatic iron stores. Deferoxamine works more rapidly and efficiently in removing liver iron than cardiac iron.[209,348] Deferiprone seems to remove iron from the heart effectively[349] despite its relative inefficiency in controlling hepatic iron content.[230,257] In the gerbil animal model, deferasirox and deferiprone were equally effective in removing cardiac iron and deferasirox removed even more hepatic iron for a given cardiac iron burden.[350] Deferasirox treatment for 1 to 2 years has also been shown to reduce cardiac iron and improve cardiac MRI T2* in patients with transfusional iron overload.[351,352] Additional studies are needed to confirm these observations and to establish the relative roles of deferiprone, deferasirox, and deferoxamine or a combination thereof in the management of patients with established iron-related heart disease.[353] In patients who have undergone BMT, improvements in left ventricular contractility and diastolic function accompany the removal of excess iron by phlebotomy.[354] Heart transplantation and combined heart–liver transplantation have been performed successfully in patients with end-stage cardiac disease.[355-357]

Sterile pericarditis occurs in some patients with massive iron overload.[358] Although pericarditis is most often attributed to hemosiderosis, an association with β-hemolytic streptococcal infection and other infectious agents has also been suggested.[359] Therapy usually consists of bed rest, treatment of infection, management of superimposed congestive heart failure, and the use of salicylates or corticosteroids. Occasionally, pericardectomy may be indicated.

Lungs

Mild abnormalities of pulmonary function are common in patients with thalassemia but rarely cause clinical problems. Some patients exhibit primarily restrictive defects[360,361]; others experience mild to moderate small airway obstruction and hyperinflation.[362-364] Most patients have a decreased maximal oxygen uptake and anaerobic threshold; these do not normalize after transfusion.[365] Postsplenectomy thrombocytosis and other prothrombotic changes can predispose to pulmonary vascular occlusion and pulmonary hypertension.[366-369] Treatment with high doses of the iron chelator deferoxamine may also be associated with acute deterioration of pulmonary function.[200,201]

Kidneys

The kidneys are frequently enlarged, partly because of extramedullary hematopoiesis and partly because of marked dilation of the renal tubules.[370] The urine is often dark brown, reflecting the excretion of products of heme catabolism.[371] The urine also contains large amounts of urates and uric acid.

Recently, the Thalassemia Clinical Research Network studied the prevalence of renal abnormalities in patients with thalassemia major and thalassemia intermedia receiving deferoxamine chelation. One-third of thalassemia patients who were not regularly transfused had abnormally high creatinine clearance. Regular transfusions were associated with a decrease in clearance (P =004). Almost one-third of patients with thalassemia had hypercalciuria, and regular transfusions were associated with an increase in the frequency and degree of hypercalciuria (P <0001). Albuminuria was found in more than half of patients but was not consistently associated with transfusion therapy. In summary, renal hyperfiltration, hypercalciuria, and albuminuria are common in patients with thalassemia. Higher transfusion intensity is associated with lower creatinine clearance but more frequent hypercalciuria.[372]

Spleen and Splenectomy

Massive splenomegaly is unusual in regularly transfused patients, but even mild or moderate splenomegaly may be associated with findings of hypersplenism, including thrombocytopenia, neutropenia, and increasing anemia. The usual indication for splenectomy is a progressive increase in transfusion requirements caused by hypersplenism. The transfusion requirements, and therefore the rates of iron loading, of splenectomized patients are often considerably less than those of patients whose spleens are intact.[278,349,373,374] A transfusion requirement of more than 180 to 200 mL/kg/yr of packed RBCs usually represents excessive RBC requirements.[373,374] For such patients, a 25% to 60% reduction in transfusion requirements after splenectomy is generally predictable. Before attributing increased transfusion requirements to hypersplenism, it is important to look for other causes, such as RBC alloimmunization or a change in the hematocrit of the units of donor blood. RBC survival studies using ^{50}Cr-labeling are not usually of value for predicting response to splenectomy. Because of the greater risk of postsplenectomy sepsis in younger patients, surgery should be deferred until after 5 years of age whenever possible. For well-transfused and well-chelated patients, splenectomy may have little benefit, and some centers have noted a significant decline in the number of patients undergoing splenectomy in recent years.

Laparoscopic splenectomy has proved safe for patients with thalassemia and has dramatically shortened the recovery time compared with open procedures.[375] Partial splenectomy and partial dearterialization of the spleen have been suggested as alternative approaches to reducing blood requirements without incurring the risk of sepsis.[376-378] The long-term benefits of this approach remain uncertain. Therapeutic embolization of the spleen avoids the need for surgery,[379-381] but this approach is frequently associated with postprocedure pain and fever and does not permit the removal of accessory spleens.

After splenectomy, striking thrombocytosis may occur, which may require thrombophilia prophylaxis or platelet deaggregating agents.[382] Increased numbers of nucleated RBCs appear in the blood, and the presence of many RBCs containing inclusion bodies composed of precipitated α-globin chains can be demonstrated by staining with methyl violet or brilliant cresyl blue.

A period of observation without transfusion after splenectomy may be helpful in identifying patients who can now maintain an acceptable hemoglobin level without regular transfusions. This approach may be particularly useful for patients whose thalassemia mutations would predict a milder clinical course. Hemoglobin levels should be monitored weekly to determine whether transfusion therapy should be reinstituted.

Patients with thalassemia major are at significant risk for the development of overwhelming, often fatal, infection after splenectomy (postsplenectomy sepsis syndrome).[383] The problem is most common in young children. *Streptococcus pneumoniae* causes two-thirds of cases; *Hemophilus influenzae* type B and *Neisseria meningitidis* account for most of the remaining infections. Typically, there is a fulminant clinical course, proceeding from mild fever and headache to hyperpyrexia, prostration, shock, and death within 6 to 12 hours. Immunization against the most common pathogens before

splenectomy, prophylaxis with antibiotics, and early assessment of fever after splenectomy have dramatically reduced the incidence of fatal postsplenectomy sepsis.

Splenectomy should generally be reserved for patients with excessive transfusion requirements from hypersplenism and difficulty controlling iron overload. A large spleen alone does not usually cause significant clinical problems and should rarely, if ever, be the sole reason for splenectomy. If possible, splenectomy should be delayed until children with thalassemia are at least 5 years old. By this time, children are more likely to have developed humoral immunity to a broad range of bacteria. Before splenectomy, polyvalent pneumococcal, meningococcal, and *H. influenzae* vaccines should be administered if they have not been given earlier in life.[384,385] Oral penicillin therapy, 250 mg twice daily, is generally used as prophylaxis against postsplenectomy infection in patients with thalassemia. However, the optimal duration of penicillin prophylaxis remains unknown, and compliance is frequently inadequate.[386] Although the risk of postsplenectomy sepsis decreases with age, it does not disappear, and fatal pneumococcal sepsis has occurred many years after removal of the spleen.[387]

Pneumococcal sepsis is not totally preventable because not all pneumococcal strains are represented in the available vaccines. In addition, penicillin-resistant strains of *S. pneumoniae* have emerged with a prevalence in the United States of 5% to 10% or even higher in some localities. Therefore, it is particularly important that patients and families be instructed to seek medical attention immediately if significant fever or other signs of infection develop.

Vitamin Supplementation

Although folic acid deficiency is uncommon in patients receiving regular transfusions, daily supplementation with 1.0 mg of folic acid is reasonable, especially if dietary intake is not optimal. Therapy with large doses of vitamin E neither improves survival of transfused RBCs nor decreases transfusion requirements.[388] Whether vitamin E supplementation decreases the toxic effects of iron overload on specific tissues remains uncertain. Zinc supplementation is appropriate for patients with clinical or laboratory findings of zinc deficiency, usually a result of intensive iron chelation therapy. One center has reported an enhancement of linear growth in children with thalassemia receiving zinc for 1 to 7 years.[389]

Survival in Patients with Thalassemia Major

Improved transfusion therapy and the consistent use of iron chelation therapy have extended the life span of patients with thalassemia major.[115,213,215,390] In a multicenter study of 1079 patients in Italy, the probability of survival to age 20 years was 96% for patients born between 1975 and 1979, the time at which chelation therapy became a regular part of the overall management of thalassemia major (Table 38-2).[213] In contrast, the probabilities of survival at 20 years of age were only 61% and 69% for those born in the periods of 1960 through 1964 and 1965 through 1969, respectively. Other investigators have shown that survival or prevention of life-threatening complications is strongly related to good chelation therapy, assessed either by compliance or by control of iron stores (Fig. 38-11).[174,207,215] The importance of good compliance with chelation therapy is further demonstrated by data from the United Kingdom showing that the probability of survival for the 1975 through 1984 birth cohort is to date not substantially different than the probability of survival for the 1965 through 1974 birth cohort.[390] The researchers attribute this poorer than expected survival rate, despite the availability of deferoxamine, to a lack of adherence to the recommended schedule of treatment with this chelator.

Table 38-2 Survival by Birth Cohort at Different Ages of Patients With Transfusion-Dependent Thalassemia

Patient Age (Years)	Cohort		
	1970-1974	1975-1979	1980-1984
10	98% (96-99)	98% (96-99)	99% (95-100)
15	95% (92-97)	97% (94-98)	98% (93-100)
20	89% (85-92)	96% (93-98)	
25	82% (77-86)

Hematopoietic Stem Cell Transplantation

The first transplantation of allogeneic hematopoietic stem cells (HSCs) derived from the BM of a human leukocyte antigen (HLA)–identical sibling donor was reported in 1982.[391] There is now extensive experience with transplantation, with well over 3000 patients having undergone transplantation.[392] The pioneering work of Lucarelli's group in Pesaro, Italy, has allowed for the prognostic classification of patients younger than the age of 17 years who receive an HLA-identical sibling donor with a preparative regimen, including busulfan, cyclophosphamide, and cyclosporine. This risk classification is based on hepatomegaly, the degree of portal fibrosis, and the regularity of prior iron chelation therapy.[393] In class 1 without adverse factors, the overall survival rate is 95%, and the event-free survival rate (without thalassemia) is 90%; class 2 patients with one or two risk factors have an 85% survival and an 81% event-free survival; and class 3 patients with all three risk factors have only 64% and 62% overall and event-free survival rates, respectively (Fig. 38-12).[393] Advances in conditioning regimens have considerably improved the outcome of class 3 patients who are younger than 17 years of age. Preparatory chemotherapeutic regimens to enhance immunosuppression and eradicate thalassemic clones using hydroxyurea, azathioprine, fludarabine, busulfan, and cyclophosphamide have increased the survival rate of class 3 patients to 93%; the rejection rate fell to 8%.[394] These favorable results have not been reproduced in the older,

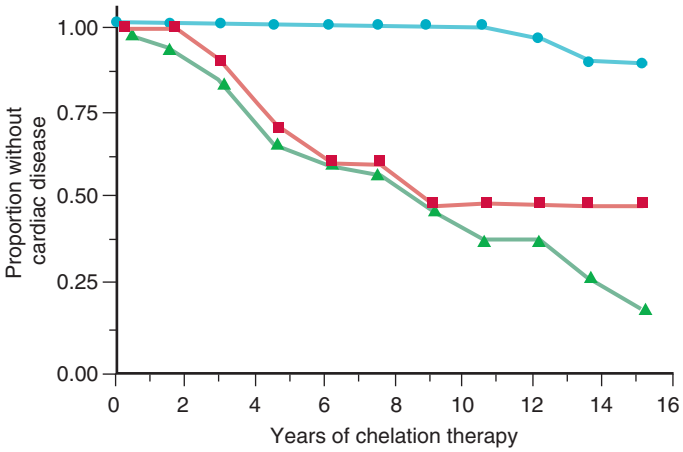

Figure 38-11 SURVIVAL WITHOUT CARDIAC DISEASE IN PATIENTS WITH THALASSEMIA MAJOR TREATED WITH DEFEROXAMINE ACCORDING TO THE PROPORTION OF SERUM FERRITIN MEASUREMENTS GREATER THAN 2500 NG/ML. The *circles* show cardiac disease-free survival among patients in whom less than 33% of ferritin measurements exceeded 2500 ng/mL; *squares* show survival among patients in whom 33% to 67% of ferritin measurements exceeded 2500 ng/mL; and *triangles* show survival among patients in whom more than 67% of ferritin measurements exceeded 2500 ng/mL. *(Adapted from Olivieri NF, Nathan DG, MacMillan JH, et al: Survival in medically treated patients with homozygous beta-thalassemia.* N Engl J Med *331:574, 1994.)*

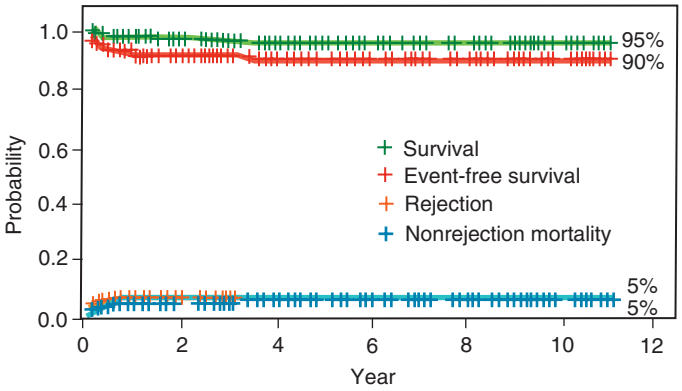

Figure 38-12 Kaplan-Meier probabilities of survival, event-free survival, rejection, and nonrejection mortality for 121 class 1 thalassemic patients younger than 17 years receiving bone marrow transplants from human leukocyte antigen–identical donors after preparation with busulfan (14 mg/kg), cyclophosphamide (200 mg/kg), and cyclosporine alone, from January 2, 1986, through April 10, 1997, and calculated on May 15, 1997. *(Adapted from Lucarelli G, Galimberti M, Giardini C, et al: Bone marrow transplantation in thalassemia.* Ann N Y Acad Sci *850:270, 1998.)*

more heavily iron-overloaded patients who remain high risk for transplant-related mortality.[395] Stem cell transplantation can fail or be lethal owing to its immunologic complications. The overall incidence of acute graft-versus-host disease (GVHD) is 17% to 32% depending on the prophylaxis regimen, and the incidence of chronic GVHD is 27% in patients receiving BM HSCs from a parental or sibling HLA-identical donor.[396]

Although HSC transplantation is the only curative therapy available, its use has been limited by cost and the rarity of HLA-identical related donors.

Building on the success of BMT for patients with thalassemia major using HLA-identical related donors, investigators have explored alternative strategies to increase the safety and availability of transplantation. In pediatric patients, transplantation of stem cells from umbilical cord blood has been associated with a reduced risk of GVHD compared with BMT.[397,398] Stem cells derived from sibling umbilical cord collections have increased in part the safety and availability of HLA-identical related donor transplantation. The probabilities of acute and chronic GVHD are decreased to 11% and 6%, respectively, in patients who receive allogeneic related cord blood transplantation.[397] However, despite the 100% overall probability of survival, disease-free survival rate was only 79%.[398]

Reports of graft rejection and mixed chimerism using cord stem cells have occurred as well as a high rate of nonengraftment with secondary rejection at a median follow-up of 49 months.[398] The size of the cord blood collection and small number of cord stem cells transplanted relative to the number required to allow engraftment, sustain hematopoiesis, and prevent graft rejections are most likely responsible for failures. Rare case reports describe successful outcome with nonrelated cord blood transplantation.

Successful use of cord blood transplantation has led to the development of the Sibling Cord Blood Donor Program in the United States, and 1617 cord blood collections have been processed for families with thalassemia. Some patients have received cord blood transplantation either alone or in combination with BM or peripheral progenitor cells.[399] In addition, BM donor registries have also developed worldwide to identify HLA-compatible unrelated donors with more that 10 million volunteers registered.

In an effort to increase the pool of potential recipients of stem cell transplantation for thalassemia, investigators have also explored the use of matched unrelated donor BMT. Extended haplotype and family segregation studies may identify suitable unrelated donors using HLA closely matched unrelated donor transplantation in thalassemia using high-resolution molecular HLA typing. La Nasa et al[400] reported 79% disease-free and 66% event-free survival, but 19% died of transplant-related complications, 41% developed grade II to IV acute GVHD, and 25% had chronic GVHD. Most of the deaths occurred in patients with heavy iron overload or hepatic complications. The results suggested that engraftment and less GVHD occurred when the recipient and donor were identical for one or two extended haplotypes.[400] Other reports also using unrelated HSCs selected according to stringent criteria of compatibility and using high-resolution molecular typing have indicated that unrelated donor transplantation may offer results comparable to those obtained with HLA-identical family donors for patients with limited iron overload.[400,401] Otherwise, the overall disease-free survival rate is only 60%, with a significant risk of chronic GVHD. The results obtained with cord blood stem cell transplantation are encouraging, but too little experience exists for definitive conclusions.[402]

Alternative unrelated matched or mismatched related donor transplantation is associated with a greater risk of immune complications. The only well-established curative therapy is allogeneic stem cell transplantation from a matched related donor. Transplantation is an important consideration in management for young thalassemia patients who have yet to accumulate excessive iron and those who have successfully controlled iron stores with chelation and who have an HLA-identical matched related donor.

The options of cord blood stem cell collection and cord blood or BMT discussions with families of the newly diagnosed are warranted as is a discussion of the long-term outcomes.

After a successful stem cell transplantation, some patients remain iron overloaded and require phlebotomy to prevent the risks of progressive hepatic fibrosis; other previously affected patients with hepatitis C require antiviral treatment[220,403] that may improve hepatic fibrosis and cirrhosis.[404]

After transplantation, some patients develop a state of mixed chimerism that may persist in 10% to 30% of patients with a predominance of host cells in the BM even though transfusion dependence may have dissipated.[405] However, 30% of patients with early mixed chimerism subsequently reject their graft.[406] Those patients with mixed chimerism and falling hemoglobin who require supportive transfusion may successfully undergo a second transplant with nonmyeloablative conditioning to restore normal hemoglobin levels.[407,408]

Subsequent investigations to evaluate the effect of nonmyeloablative conditioning regimens as a primary approach to transplantation with the objective of causing a chimeric outcome have been attempted and are of questionable benefit.[401,409,410]

Allogeneic HSC transplantation from a partially HLA-matched relative has also been investigated, with much less encouraging results. Gaziev et al[395] reported early or late graft-versus-host and graft failure in 55% of partial HLA familial matched without significant correlation between the degree of antigen disparities and graft failure. GVHD was a major factor contributing to death (50%) followed by infection (30%). The probability of overall survival and transfusion dependence were 65% and 21%, respectively, with a median follow-up at 2.5 years for surviving patients.[395]

In view of the available evidence, stem cell transplantation from a partially HLA-matched relative is not routinely advisable, although it may be considered in extreme situations when transfusion support is impossible or life threatening when a patient is completely noncompliant with any type of iron chelation therapy.

The excellent results of BMT in young patients with thalassemia who have yet to accumulate excessive iron or who have successfully controlled iron stores have made transplantation an important consideration in their management. The option of BM or umbilical cord blood transplantation should be discussed with families of newly diagnosed patients with thalassemia major and should be compared with long-term transfusion and chelation therapy. Both approaches should be addressed in terms of currently identified risks and benefits, the likelihood of future improvements, and the potential for new treatments such as gene therapy. In some centers, tissue typing of immediate family members is undertaken routinely, but in others, this evaluation is performed only if the family wishes to consider transplantation as a treatment option. On the basis of the positive results with umbilical cord blood transplantation, parents of children

with thalassemia should be encouraged to collect and store cord blood with future pregnancies.[399,411] The use of preimplantation diagnosis to identify an HLA-identical embryo unaffected with the sibling's blood disorder poses significant ethical dilemmas but has been used to create suitable donors for cord blood or BMT in cases of other hematologic diseases.[412-416] A related and also controversial approach is the use of both fetal and family HLA typing in pregnancies at risk of homozygous thalassemia to determine whether an HLA-identical sibling is available as a potential BM donor if the fetus is affected and carried to term.[417,418]

The rate of success for BMT in children with more significant iron overload, in adults, and in patients without an HLA-identical sibling or parent suggests caution in the use of this approach. Transplantation has been recommended for such patients if they show progressive deterioration with conventional transfusion and chelation therapy. The availability of new chelating agents may significantly affect this balance, as may improvements in transplantation.

Long-term complications of stem cell transplantation have also been reported, including gonadal dysfunction and fertility as well as growth failure and other endocrinopathies.[419,420]

In conclusion, HSC transplantation with the use of matched related or unrelated donors is an alternative to standard transfusion and chelation therapy and generally results in excellent outcomes for low-risk patients. However, there are small risks of serious complications including death, graft failure or rejection, GVHD as well as growth failure, infertility, and other endocrinopathies. Stem cell transplantation should be considered for class 1 and 2 children who have suitable donors. Unrelated HLA-matched donors, although an acceptable source of allogeneic stem cell for other conditions, are not yet considered suitable for children with thalassemia because of the relatively long-term survival associated with conventional therapy. Owing to the considerable risks and experiences of transplantation as well as the prospect of 2 or 3 decades of life with conventional management, discussions with the families of children who are potential candidates for transplant should be thorough.

Transplantation for those class 3 older patients and adults fare less well[421-423] and should be considered only for those who have a suitable donor or deteriorate with conventional treatment.[113]

Experimental Therapies

Enhancement of β and γ Gene Expression

For many years, much effort has focused on stimulation of γ-globin gene expression or replacement of defective β-globin genes. Enhanced γ-globin gene expression would ameliorate the unbalanced globin chain synthesis and replace the missing adult hemoglobin with fetal hemoglobin.

Active γ-globin genes are hypomethylated in utero but are methylated and inactive after birth. Hypomethylation of the γ-globin genes can be induced by the drug 5-azacytidine; indeed, short-term administration of this drug produced the predicted effect in vivo.[424-426] Despite much subsequent experimental work, it remains unclear whether the effect was attributable to direct stimulation of fetal genes by demethylation or to recruitment and accelerated differentiation of primitive burst-forming unit–erythroid (BFU-E) progenitor cells, which have greater potential to produce Hb F.[427-429] Hydroxyurea has an effect on BFU-E similar to that of 5-azacytidine and is a safer drug for long-term use.[428,430] Short-term as well as longer trials with hydroxyurea have been reported in a number of patients with thalassemia.[431-438] Hb F levels frequently increase without a proportionate increase in total hemoglobin level. A small improvement in total hemoglobin level occurs in some patients with thalassemia intermedia but usually does not exceed 1 to 2 g/dL.[435,436] Some patients report improvement in their overall sense of well-being even in the absence of an improvement in the anemia.[435] This may be a result of suppression of abnormal erythropoiesis, an effect that may also explain the value of hydroxyurea in the treatment of extramedullary hematopoietic masses (see later discussion).[439] Although one patient with thalassemia major had sufficient improvement in his hemoglobin level to end his dependency on regular transfusions,[437] most transfusion-dependent patients have shown no clinical benefit. In a review of hydroxyurea therapy, Steinberg and Rodgers[438] identified 52 patients with β-thalassemia who were treated with a variety of regimens. They concluded that hydroxyurea alone had only a modest effect in thalassemia intermedia and did not look promising for thalassemia major.[440]

Recombinant erythropoietin has produced inconsistent responses in patients with thalassemia intermedia.[441-445] When the series are combined, approximately 40% of patients have an increase in hemoglobin level of 2 to 3 g/dL. Fetal hemoglobin levels are unchanged. The potentially adverse consequences of further stimulation of an already hyperactive BM are uncertain. Erythropoietin has shown little benefit overall in patients with thalassemia major, although there are occasional reports of patients whose transfusion requirements were reduced or eliminated.[444,446]

Butyrate and other short-chain fatty acids have been demonstrated to augment Hb F production in various animal model systems as well as in humans.[447-449] These compounds are believed to act by altering chromatin configuration, perhaps because of inhibition of histone deacetylatase.[450-454] Short-term treatment with intravenous infusions of arginine butyrate in a limited number of cases[451,452] resulted in a marked increase in γ/α-globin chain synthetic ratios,[450,455] but others did not have a sustained hematologic response.[456] In yet another trial, administration of arginine butyrate intravenously in pulsed fashion to patients with sickle cell anemia and thalassemia resulted in favorable hematologic responses, raising the possibility of hematologic toxicity and suboptimal responses with continuous infusions of the drug.[457] Orally absorbable butyric acid compounds, including sodium phenylbutyrate and isobutyramide, also have been reported to result in an increase in F-cell and γ-globin chain production, but the effect was not as sustained or as quantitatively comparable to that originally obtained with intravenous arginine butyrate.[430,439,458-464] A study of isobutyramide in cases of thalassemia major found a reduction in transfusion requirements in two of eight patients. No severe toxic side effects were observed in these relatively short-term trials in humans, but the infusion of high doses of butyrate into baboons did result in significant neurologic toxic effects. Further studies will be required to assess the long-term safety and efficacy of therapy with butyrate. Most recently, a new fetal hemoglobin inducer, HQK-1001, has been identified, and its erythropoietic stimulatory efforts are being studied.[465]

Various combinations of hydroxyurea, butyrate, and erythropoietin have been used to try to achieve hematologic benefits that cannot be achieved with a single agent.[450] The addition of hydroxyurea to therapy with sodium phenylbutyrate led to a further increase in hemoglobin level in a patient with homozygous Lepore. However, the combination of sodium phenylbutyrate and hydroxyurea was no better than hydroxyurea alone in other patients with thalassemia intermedia.[436] Combined therapy with hydroxyurea and erythropoietin produced marginally higher hemoglobin levels than either drug alone in only two of seven patients with thalassemia intermedia.[442] A more dramatic rise in hemoglobin level occurred in a patient with thalassemia major, but the relative contributions of pharmacologic therapy and splenectomy are unclear.

Decitabine has been shown to result in a considerable sustained increase of Hb F and total hemoglobin in patients with sickle cell disease with the low likelihood of neutropenia and may have a similar effect in thalassemia but its therapeutic efficacy remains to be proven.[466,467] A pilot study of subcutaneous decitabine in β-thalassemia intermedia has shown somewhat favorable changes in hemoglobin levels ($P = .004$) and absolute fetal hemoglobin levels ($P = .003$).[468]

Although the pharmacologic enhancement of fetal hemoglobin production remains an attractive strategy in the management of thalassemia, the results to date strongly suggest the need for new agents or new combinations of agents. At present, the primary clinical application of this approach is in the management of severely affected patients who are unable to be transfused because of multiple alloantibodies or because of autoantibodies. This approach might also be

used for patients with thalassemia intermedia who develop a need for frequent transfusions. However, studies suggest that the current approaches to fetal hemoglobin enhancement will usually be unsuccessful in either of these situations.

Another potential strategy is to develop techniques to silence HbF suppression. Recently, the knock down of BCL11A expression resulted in the reactivation of HbF expression.[469] Other important molecular targets to induce HbF include KLF1, MYB, SOX6, MiRNAs, and histone acetylase, which may lead to other targeted approaches to enhance HbF.[470-478] BCL11A is a zinc-finger transcriptional repressor active in erythroid cells and in other hematopoietic lineages.[479] Several studies indicate that BCL11A silences γ-globin.[479-481] BCL11A does not bind the γ-globin promoter but the LCR and different intergenic regions in the globin locus that were previously tied with γ-globin repression.[479,482-485] KLF1 (also known as EKLF) is an erythroid transcription factor activating BCL11a and playing a major role in the switch from fetal to adult hemoglobin.[486-489] Thalassemia intermedia patients with mutations in the CACCC box of the β-globin promoter (which is recognized by KLF1) demonstrate significant elevation of HbF.[490,491] An additional locus highlighted by GWAS is the intergenic interval between HBS1L and MYB.[492-495] More recently, it has been demonstrated that knockdown of c-Myb was associated with decreased expression of KLF1.[496] In conclusion, new key regulators of the globin switch have been identified that may be used to develop new and more powerful drugs aimed at increasing fetal hemoglobin synthesis.

β-Globin Gene Transfer

Cure of thalassemia by genetic transfer of the normal β-globin gene into the pluripotent HSC awaits further advances in molecular biology but is a goal of the foreseeable future.[497] β-Globin gene transfer and expression has been accomplished in thalassemia murine models, which have demonstrated that retroviral vectors, specifically lentiviral vectors, are capable of transferring the human β-globin gene sequences and its promoter regions into murine stem cells[498,499] and into long-term repopulating hematopoietic cells of primates and humans.[500,501] Studies of safe and efficient specific targeting vectors in humans are ongoing.[502] Techniques for obtaining long-term expression of human globin genes after transfer into murine HSCs have been developed.[503,504] Thus, there has been remarkable success in the use of globin gene transfer for "therapy" of murine models of β-thalassemia and sickle cell anemia.[497,498,503,505-507] However, clinical trials have suffered from problems of vector instability, low viral titers, and variable expression of globin genes.[508] Additional safety modifications to prevent potential genotoxic effects have been studied, including the use of insulators or genetic elements with enhancer-blocking properties to increase the safety of clinical trials.[509-511] Genetic elements with enhancer-blocking properties, such as insulators, could increase the safety of the clinical trails. These elements have been investigated to shelter the vector from the repressive influence of flanking chromatin by blocking interactions between regulatory elements within the vector and chromosomal elements at the site of integration.[509-511] This property of insulators can also be harnessed to diminish the risk that the vector will activate a neighboring oncogene.[508,512] These formidable problems need to be solved before it becomes routinely possible to transfer and effectively express globin genes in human HSCs; ensure their safe and active expression at effective levels; and preserve normal growth, differentiation, and proliferation of the genetically transformed stem cell.[513-517] Nevertheless, protocols have been developed to carry out gene transfer experiments in humans.[518] A phase I human gene therapy clinical trial for hemoglobinopathies was initiated in France in 2007.[519] To date, one compound heterozygote patient with β-E thalassemia received a lentiviral vector with a normal β-globin gene who after gene transfer is transfusion independent and is producing the "therapeutic" vector hemoglobin as well as fetal and embryonic hemoglobins.[519] This trial used a lentiviral vector that expresses an adult β-globin gene flanked by two copies of the 250-base-pair core of the cHS4 chromatin insulator implanted in the U3 region of the 3′ long terminal repeat. After gene transfer, the patient became transfusion independent. However, the therapeutic hemoglobin in this patient contributed only one-third of the total hemoglobin synthesized; the embryonic and fetal hemoglobins accounted equally for the remaining hemoglobin. Therefore, the success of this first trial was made possible by the additive effect of transgenic β-globin chains synthesized by the vector and those (fetal and adult) made by the patient's cells. Thus, without the support of endogenous hemoglobins, the gene transfer would not have allowed this patient to become transfusion independent. Further work is currently planned, and studies are being conducted to better predict the outcome of gene transfer.[518]

iPS Cells and Gene Correction

Alternatively, somatic cells reprogrammed to induced pluripotent stem cells (iPSCs) might also provide a possible new approach to treat β-thalassemia and sickle cell disease.[520] Currently, robust generation of iPSCs requires the introduction and integration of genes encoding the transcriptional factors OCT3/4, SOX2 with either KLF4 and c-MYC or NANOG and LIN28.[521-523] Ye and coworkers[520] have shown that iPSCs can be generated from cells derived from skin fibroblasts, amniotic fluid, or chorionic villus sampling of patients with β-thalassemia and subsequently differentiated into hematopoietic cells that synthesized hemoglobin.

However, these iPS cells will need to be corrected for the β-globin mutation before they can be redifferentiated to HSC hemoglobin producing RBCs. Homologous recombination (HR) in embryonic and iPSCs for the cure of hemoglobinopathies has several potential advantages over conventional gene therapy, including eliminating the need for immunosuppression, avoiding the risk of insertional mutagenesis by therapeutic vectors, and maintaining expression of the corrected gene by endogenous control elements rather than a constitutive promoter. Wu et al[524] and Chang et al[525]'s laboratories used HR to generate iPSCs from, respectively, a β-thalassemic patient and sickle mice and correct their mutations. Moreover, using a humanized sickle cell disease (SCD) mouse model, Jaenisch's laboratory demonstrated that mice can be rescued after transplantation with hematopoietic progenitors obtained in vitro from autologous iPSCs. This was achieved after correction of the human sickle hemoglobin allele by gene-specific targeting.[526] Furthermore, proof of principle that the β-globin gene can be repaired in human iPSCs was provided by two groups.[527,528] They achieved correction of the β-globin gene by HR in iPSCs derived from a SCD patient using specific β-globin zinc finger nucleases engineered to specifically stimulate HR at the β-globin locus. Importantly, this work strongly supports the rationale to generate corrected iPSCs using HR, showing that this technique is feasible and can lead to the production of corrected iPSCs. However, additional studies need to be done before this approach can be used for humans.

Thalassemia Intermedia

Approximately 10% of patients with homozygous β-thalassemia exhibit a phenotype characterized by intermediate hematologic severity.[1-4] The balance of globin chain synthesis is better than in typical thalassemia major because of a less severe defect in β-globin chain synthesis, a decrease in α-globin chain synthesis as well as β-globin chain synthesis, or an increase in γ-globin chain synthesis. For example, homozygous β-thalassemia in African Americans, Portuguese, and other populations may be relatively mild, at least for the first 2 decades of life.[529-531] Homozygotes or mixed heterozygotes for forms of β-thalassemia associated with normal Hb A_2 and normal Hb F (silent carrier state) also tend to have mild to moderate disease.[532,533] Certain patients have a milder clinical phenotype because they have co-inherited a form of α-thalassemia[13-15] or because they carry one (or two) β-thalassemia chromosome(s) with a greater than usual potential for high levels of γ-globin gene expression.

The ability to maintain a hemoglobin level compatible with comfortable survival in the absence of regular transfusions is the generally accepted criterion for the diagnosis of thalassemia intermedia. In other words, distinguishing between thalassemia major and thalassemia intermedia, which in turn is the distinction between initiating a regular transfusion program or not, requires consideration of the hemoglobin level and the quality of life. These two parameters do not have a predictable relationship. Patients with thalassemia and hemoglobin levels of 7 g/dL may be relatively symptom free, but patients with hemoglobin levels of 9 g/dL may have numerous problems related to ineffective erythropoiesis. Thus, the assessment of the patient rather than the hemoglobin level alone is essential in deciding who does not require regular transfusions and therefore, by definition, has thalassemia intermedia. Some nontransfused patients have normal growth and sexual development, few medical problems, and normal or near-normal survival rates. However, others develop disfiguring facial changes, markedly delayed growth and sexual maturation, heart failure, severe osteoporosis, repeated fractures, arthritis, and massive splenomegaly. Calling the condition of this latter group "thalassemia intermedia" implies a milder disease than thalassemia major but, in fact, the patients' quality of life does not compare favorably with the quality of life of patients with thalassemia major. Nonetheless, many families and physicians are reluctant to initiate a chronic transfusion program because of concern about the risks of long-term transfusion therapy and the inevitable need for iron chelation therapy. If the decision is made to manage the patient initially without regular transfusions, regular reassessments of the patient's clinical condition, including appearance, growth, and development, and bone expansion are crucial.[534] Short-term transfusion therapy may be useful during pregnancy or in the management of cardiac and other serious complications. The need for regular transfusions often develops in adults with thalassemia intermedia because of a further decline in the hemoglobin level or a growing intolerance of the anemia.[535]

Even in the absence of regular transfusions, many patients develop progressive iron overload because of increased absorption of dietary iron induced by ineffective erythropoiesis and, in many cases, the intermittent administration of RBC transfusions. By the third or fourth decade, the total iron burden may attain the levels seen in transfusion-dependent patients.[536] Ferritin levels may underestimate the degree of tissue iron loading in thalassemia intermedia, and assessment of liver iron concentration is more helpful in determining the need for chelation therapy. Deferoxamine as well as the orally active iron chelator deferiprone (L1) has proved effective in thalassemia intermedia.[537,538]

Splenectomy raises the hemoglobin level by 1 to 3 g/dL in many patients with thalassemia intermedia.[539,540] Removal of the spleen should receive careful consideration as a potential alternative to beginning transfusion therapy. As noted earlier, for patients who undergo splenectomy while on a chronic transfusion program, a period of careful monitoring of the hemoglobin level after surgery may occasionally identify individuals who are no longer transfusion dependent and who can therefore be reclassified as having thalassemia intermedia.

Thromboembolic events represent a major complication of thalassemia intermedia, occurring in 10% to 34% of patients.[369,541] These events include stroke, pulmonary embolism, portal vein thrombosis, and deep vein thrombosis of the legs. A hypercoagulable state may also contribute to the pulmonary hypertension that commonly occurs in patients with thalassemia intermedia and is the primary cause of congestive heart failure.[542] Splenectomy is a risk factor for thromboembolic events in patients with thalassemia intermedia, resulting in thrombocytosis and allowing the prolonged circulation of damaged RBCs that generate increased amounts of thrombin.[369] Some investigators consider the risk of thromboembolic events after splenectomy for thalassemia intermedia to be sufficiently high to warrant short-term anticoagulation in the perioperative period and during pregnancy.[369] Oral contraceptives should be used with extreme caution, if at all.

Extension of hematopoietic tissue beyond the confines of the bones occurs in patients with thalassemia intermedia as a result of the intense erythropoiesis. This complication occurs less frequently in patients with thalassemia major because of the partial suppression of erythropoiesis by regular transfusions. Masses of extramedullary hematopoietic tissue develop in the spinal epidural space, thorax, cranium, pelvis, and elsewhere.[439,543-553] These masses may be detected as incidental findings on imaging studies of the chest or abdomen.[544-550] In other instances, the masses produce symptoms by compressing neighboring structures. For example, patients with extramedullary hematopoietic masses may develop paraplegia from spinal cord compression or loss of visual acuity or visual fields caused by optic nerve compression.[543,546,552,553] Additional clinical presentations of hematopoietic masses include pleural effusions and upper airway obstruction.[548,549,551] Initiation of regular transfusions for patients with thalassemia intermedia or intensification of the ongoing transfusion program for patients with thalassemia major reduces the size of extramedullary hematopoietic masses and helps to prevent recurrences. Therapy with hydroxyurea has also been associated with shrinkage of hematopoietic masses.[439] Low-dose radiation therapy provides more immediate relief and may be particularly useful for acute neurologic complications.[554]

Reconstruction of the maxilla may be needed for some patients with thalassemia intermedia to provide cosmetic improvement of facial asymmetry and malocclusion.[555] Gallstones regularly occur by the second decade of life.[556] Leg ulcers often occur in late adolescence or afterward and may require RBC transfusions as well as local measures for healing. Because of the marked BM hyperplasia, supplementation with folic acid is necessary to prevent megaloblastic anemia. Aplastic crises associated with parvovirus or other infections may result in exacerbations of the anemia.

Some patients with heterozygous β-thalassemia will have a moderately severe clinical disorder, with anemia, hemolysis, and splenomegaly. Some of these patients carry a greater than normal number of α-globin genes as a result of triplication of one of the α-globin gene loci: ααα/αα.[34,404,557,558] However, most heterozygous patients with triplicated α-globin gene loci are clinically similar to those with the simple β-thalassemia trait. Most patients with severe heterozygous β-thalassemia have so-called dominant β-thalassemia, which is attributable to the inheritance of a gene for a β-thalassemia hemoglobinopathy associated with a structurally abnormal, unstable, β-globin chain that may form inclusion bodies.[16,17] For heterozygotes with disease of unusual clinical severity, splenectomy may be beneficial.

β-Thalassemia Minor (Thalassemia Trait)

Inheritance of a single β-thalassemia allele usually results in a mild hypochromic microcytic anemia. The hemoglobin level averages 1 or 2 g/dL lower than that seen in normal persons of the same age and gender. Hb F levels decline more slowly than usual in the first year of life, and the diagnostic elevated Hb A_2 levels are established by approximately 6 months of age.[559-561] Strong intrafamilial correlations of both Hb A_2 and mean corpuscular volume (MCV) are noted.[562,563] Osmotic fragility is decreased; indeed, a one-tube osmotic fragility test has been used in the past for mass screening.[560] The RBC count is increased or normal. The RBCs are characteristically hypochromic (mean corpuscular hemoglobin <26 pg) and microcytic (MCV <75 fL). The smear shows varying numbers of target cells, poikilocytes, ovalocytes, and basophilic stippling (Fig. 38-13). The reticulocyte count is normal or slightly elevated. RBC survival is normal, iron utilization is decreased, and slight IE is present.[561] Most patients are asymptomatic. Many patients who have thalassemia trait are erroneously believed to have iron deficiency. Testing to distinguish these two disorders is important for genetic counseling of carriers of thalassemia trait, for the avoidance of unnecessary investigations in patients incorrectly assumed to have iron deficiency and to prevent unwarranted supplementation with iron. Although a variety of indices calculated from blood count parameters have been suggested to differentiate thalassemia from iron deficiency, each has some degree of inaccuracy; most are no better than the MCV alone.[563,564] In general, the MCV is rarely greater than 75 fL or the hematocrit less than 30 in patients with β-thalassemia trait. In cases of iron

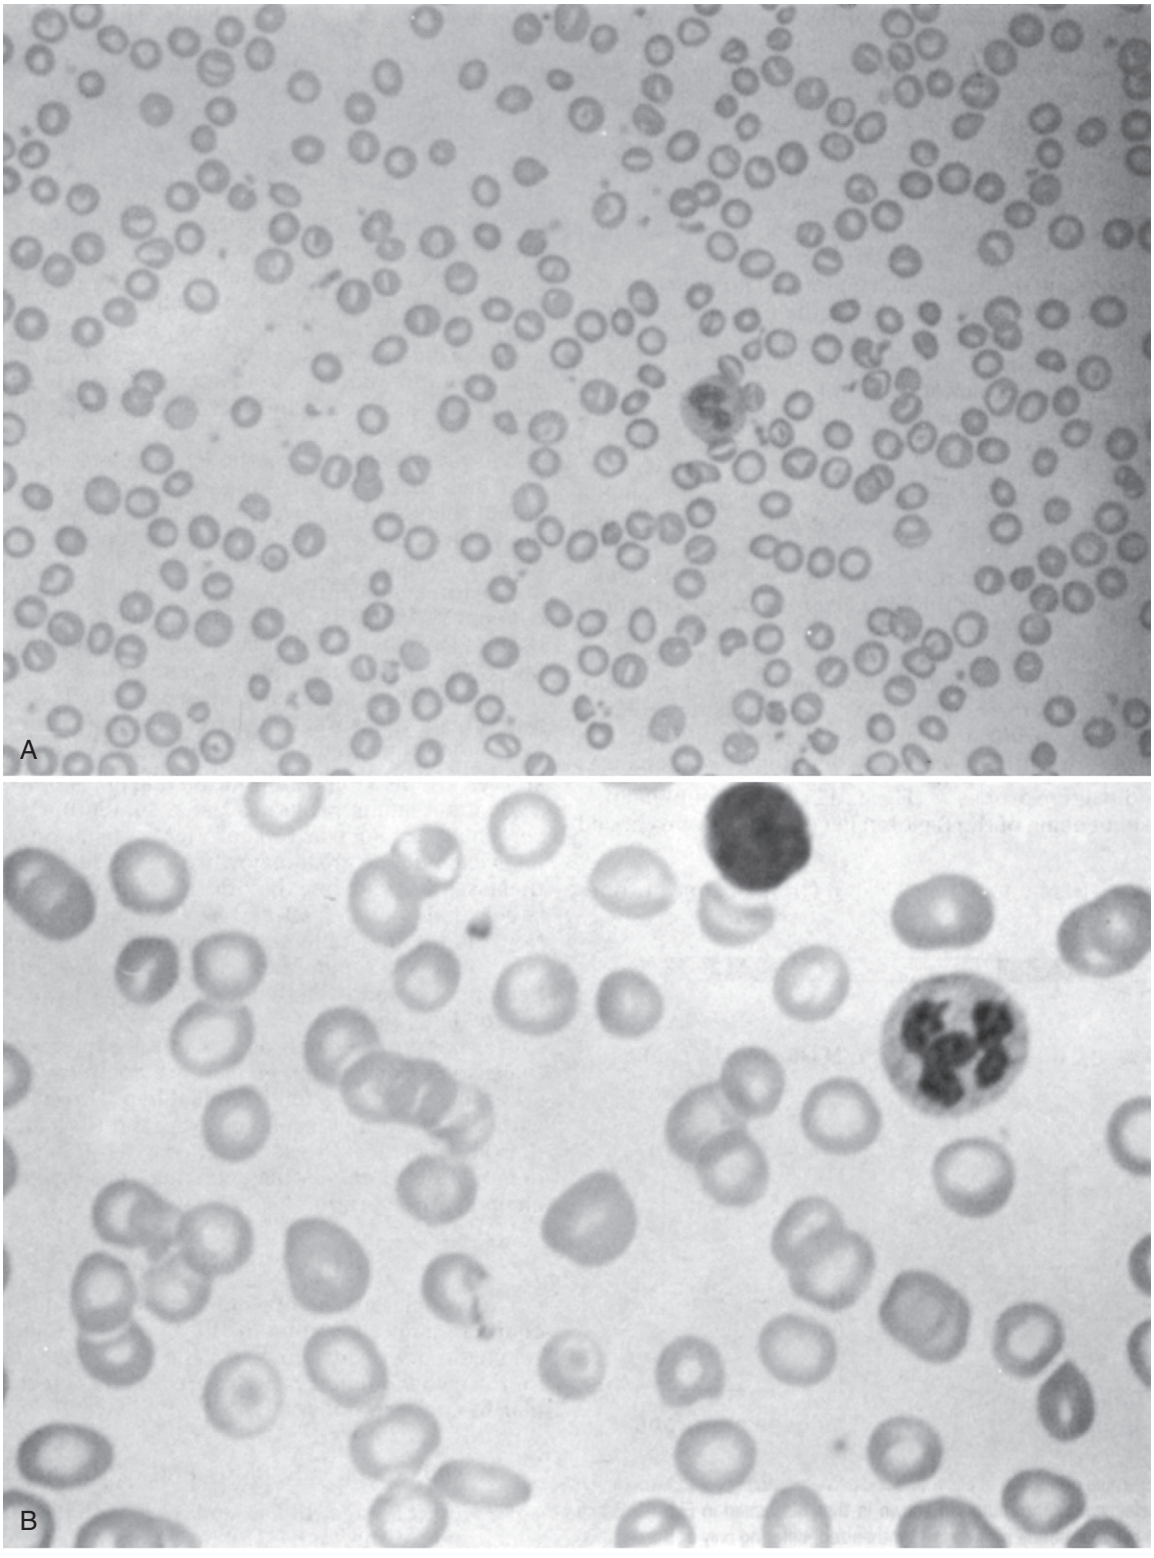

Figure 38-13 MORPHOLOGY OF THE PERIPHERAL BLOOD FILM IN A PATIENT WITH HETEROZYGOUS β-THALASSEMIA (**A**) AND A PATIENT WITH HETEROZYGOUS α-THALASSEMIA (**B**). Note the profound hypochromia and microcytosis and the many target cells. *(From Pearson HA, Benz EJ Jr: Thalassemia syndromes. In Miller DR, Baehner RL, McMillan CW, editors:* Smith's blood diseases of infancy and childhood*, ed 5, St. Louis, 1984, CV Mosby, p 439.)*

deficiency, the hematocrit level usually falls to less than 30 before the MCV falls to less than 80 fL. Free erythrocyte porphyrin levels are normal in patients with thalassemia trait but are elevated in patients with iron deficiency (see Chapter 34).[1] Specific studies for iron deficiency, such as the serum iron level and total iron-binding capacity or the serum ferritin level, help to prevent misdiagnosis.

During pregnancy, the anemia of thalassemia trait often becomes more severe, but transfusions are rarely necessary. Because iron deficiency may occur during pregnancy, iron supplementation has been advised to avoid compounding the causes of anemia.[565,566]

There may be characteristic racial differences in the hematologic severity of β-thalassemia trait. In African Americans, the condition

is invariably milder, RBC morphologic abnormalities are less marked, and β/α synthetic ratios are higher than in whites and Asians with the trait.[567]

The diagnosis of β-thalassemia trait is established in most instances by the demonstration of altered proportions of Hb A_2. The level of Hb A_2 in β-thalassemia trait averages 5.1% (range, 3.5%-7.0%), approximately twice the normal level (1.5%-3.5%); the Hb A_2 to Hb A_1 ratio is 1 : 20 instead of the normal 1 : 40. This increase is probably attributable to a posttranslational (assembly) phenomenon with increased opportunity for δ-globin chains to combine with α-globin chains in the face of β-globin chain deficiency. If concomitant iron-deficiency anemia occurs, Hb A_2 levels may fall, sometimes into the normal range.[568]

The Hb F levels are inconsistently elevated in β-thalassemia. In approximately half of cases, Hb F is within the normal range (<2.0%); in the remainder, it is moderately elevated (2.1%-5.0%). However, in almost every instance, a minor population of RBCs (F cells) containing substantial amounts of Hb F can be demonstrated by the Kleihauer technique.[1] Rarely, an individual with heterozygous thalassemia, as evidenced by a reduced β/α synthetic ratio or by virtue of having a child with thalassemia intermedia or major, has normal Hb A_2, Hb F, and hemoglobin electrophoresis, with minor (quiet carrier) or no (silent carrier) hematologic changes.[533] Rare individuals have been encountered who exhibit characteristically abnormal RBC morphology but normal levels of Hb A2 and Hb F.[1] Such individuals are probably carriers of γδβ-thalassemia.[1] Iron deficiency must be excluded and globin-chain synthesis or molecular studies done to establish a diagnosis with certainty.

The diagnosis of thalassemia trait assumes particular importance in women who are pregnant or considering pregnancy because of the potential for having a child with thalassemia major. The presence of a low MCV should be investigated further with levels of Hb A_2 and Hb F, as well as a hemoglobin electrophoresis to look for thalassemic variants such as Hb E and Hb Lepore (see later discussion). If either the father or the mother is known to have thalassemia trait, the other person should be assessed using these more definitive studies rather than the MCV alone.

Prenatal Diagnosis of β-Thalassemia

Thalassemia mutations can now be routinely and reliably diagnosed by using fetal DNA obtained between the 8th and 18th weeks of gestation. The most reliable methods are based on identification of the abnormal gene by direct DNA analysis.[22,569,570] Both amniocentesis and chorionic villus sampling have been used with success. In experienced hands, the latter method is preferable because adequate amounts of DNA can be obtained safely at an earlier gestational age. New techniques have been developed for obtaining fetal DNA for prenatal diagnosis either directly from maternal plasma or by the isolation of fetal nucleated RBCs from maternal peripheral blood.[566,571,572] The DNA is analyzed by a variety of polymerase chain reaction (PCR)–based or other methods for the presence of the thalassemia mutation.

The heterogeneity of thalassemia mutations complicates the approach to antenatal diagnosis. More than 175 independent mutations can cause β-thalassemia. However, a number of factors have improved the speed, efficacy, and reliability of DNA diagnosis. Extensive surveys of most populations in which these alleles are frequent have revealed that approximately 15 β-thalassemia mutations account for more than 90% of individuals affected worldwide. Within any given ethnic group, three to six mutations usually account for the vast majority of severe cases (see Table 38-1).[22] One can thus customize the search for mutations according to the ethnic origins of the family at risk. PCR techniques and exquisitely precise hybridization assays (allele-specific oligonucleotide hybridization), which detect single-base changes with great reliability, can now be combined to permit screening of minute DNA samples for several mutations very rapidly (Fig. 38-14). This procedure can also be done using nonradioactive oligonucleotide probes immobilized to filters, so-called

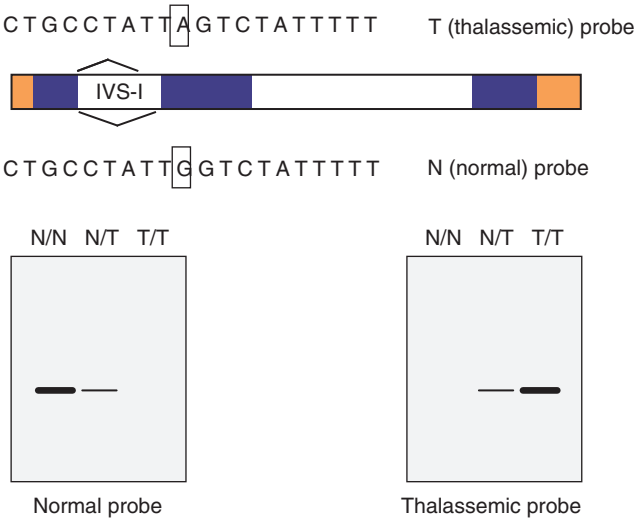

Figure 38-14 EXAMPLE OF THE USE OF ALLELE-SPECIFIC OLIGONUCLEOTIDE PROBES FOR DIAGNOSIS OF A COMMON FORM OF β-THALASSEMIA. The mutation shown is that discussed in Figure 38-2 and the text. Two oligonucleotide probes are synthesized, differing only at the position of the mutation. When hybridized under sufficiently stringent conditions, each probe will anneal only to the gene that is perfectly complementary by Watson-Crick base pairing. Thus, a homozygous normal fetal DNA sample (N/N) will anneal only to the normal probe, homozygous β-thalassemic DNA (T/T) only to the thalassemic probe, and DNA from a heterozygote (N/T) to both probes but with a reduced intensity to each. *(Adapted from High KA, Benz EJ Jr: The ABCs of molecular genetics: A haematologist's introduction. In Hoffbrand AV, editor:* Recent advances in haematology, *New York, 1985, Churchill Livingston, p 25.)*

reverse dot blot analysis.[573,574] Single-base mutations can also be detected by the PCR technique called amplification refractory mutation system (ARMS).[570,575] An amplification and direct sequencing of the β-globin genes (in cases in which the mutation is unknown) can also be carried out rapidly by use of PCR techniques.

Genetic counseling and antenatal diagnosis should be offered to all families at risk for severe α- or β-thalassemia. Prenatal diagnosis is one component of large-scale screening, education, and genetic counseling programs that are active in Italy, Greece, Cyprus, and other areas where the frequency of thalassemia is very high.[576] In some countries, particularly those with a high rate of consanguineous marriages, screening efforts can be refined to gain further efficiency in identifying at-risk couples.[577] Comprehensive programs of education, screening, and diagnosis have dramatically decreased the incidence of thalassemia major births in several countries (Fig. 38-15),[576,578,579] but they require a critical mass of expert professionals and laboratory backup. Voluntary informed participation, confidentiality of results, and meaningful counseling must be ensured.

α-THALASSEMIA SYNDROMES

The α-thalassemias are more difficult to diagnose because characteristic elevations in Hb A_2 or Hb F, seen in many cases of β-thalassemia, do not occur. However, the gene deletions responsible for the most common varieties are readily detectable by molecular biology methods.[580]

Molecular Pathology and Pathophysiology

The four classic α-thalassemia syndromes are α^+-thalassemia trait, in which one of the four α-globin genes fails to function; α°-thalassemia trait, with two dysfunctional genes; Hb H disease, with three affected genes; and hydrops fetalis with Hb Bart, in which all four genes are defective. In the older literature, α°- and α^{++}-thalassemia are referred

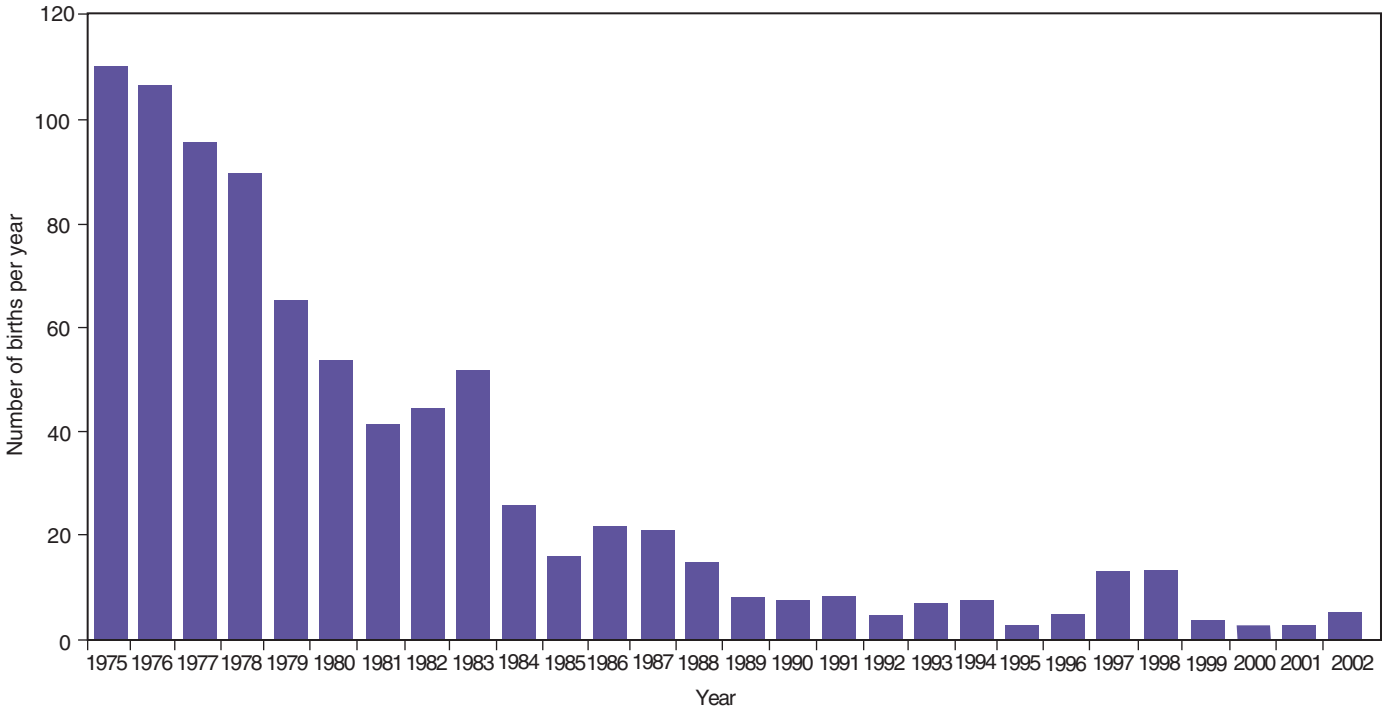

Figure 38-15 DECLINING RATE OF BIRTH OF INFANTS HOMOZYGOUS FOR β-THALASSEMIA IN SARDINIA SINCE 1975, WHEN A COMPREHENSIVE SCREENING PROGRAM BEGAN. *(Adapted from Cao A, Galanello R: Effect of consanguinity on screening for thalassemia.* N Engl J Med *347:1200, 2002.)*

to as α-thalassemia-1 and α-thalassemia-2, respectively. These syndromes are usually caused by deletion of one, two, three, or all four of the α-globin genes, respectively (Fig. 38-16). Nondeletional forms of α-thalassemia, which account for 15% to 20% of patients, arise from mutations similar to those described for β-thalassemia.[581,582] Fig. 38-17 illustrates the different α-thalassemia mutations and phenotypes. Structurally abnormal hemoglobins have also been associated with α-thalassemia. The Quong Sze α-globin chain ($\alpha^{125Leu \rightarrow Pro}$) is exceedingly labile and is destroyed so rapidly after its synthesis that no hemoglobin tetramers containing the mutant α chain can be formed.[583]

α^+-Thalassemia trait is an asymptomatic silent carrier state that is commonly associated with the deletion of a single α-globin gene. Offspring of an individual with α^+-thalassemia whose spouse has α°-thalassemia trait can inherit a form of α-thalassemia more severe than either of these, namely Hb H disease.

α°-Thalassemia trait results from deletion or nonfunction of two α-globin alleles. In Asian and Mediterranean populations, a deletion that removes both loci from the same chromosome (*cis* deletion) is common[581,582]; homozygosity for α^+-thalassemia (*trans* deletion) is also seen. In African Americans, both α-globin genes are only rarely deleted in *cis,* but homozygosity for α^+-thalassemia (*trans* deletion) is quite common.[584] Both genotypes produce asymptomatic hypochromia and microcytosis. Hb H disease usually results from coinheritance of the *cis* α°-thalassemia deletion and α^+-thalassemia trait. α-Globin chain production is only 25% to 30% of normal; excess γ-globin chains accumulate during gestation and excess β-globin chains during adult life (see Fig. 38-17). The unpaired β-globin chains are somewhat more soluble than the excess α-globin chains that accumulate in cases of β-thalassemia, forming recognizable β4 tetramers designated as Hb H. Hb H forms relatively few inclusions in erythroblasts; rather, it precipitates slowly within mature circulating RBCs. Patients with Hb H disease thus have a moderately severe hemolytic anemia but relatively little IE. Patients usually survive into adult life. These clinical observations illustrate the central role of unpaired globin chains and IE as determinants of clinical severity.

Hydrops fetalis with Hb Bart results from the homozygous state for the α°-thalassemia *cis* deletion. The α-globin genes are totally absent; no α-globin is produced, so no physiologically useful hemoglobin accumulates beyond the embryonic stage. Free γ-globin chains accumulate, forming γ_4 tetramers called Hb Bart (see Fig. 35-13). Hb Bart has an extraordinarily high oxygen affinity comparable with that of myoglobin. It binds oxygen delivered to the placenta but releases almost none of it to fetal tissues. Severe hypoxia occurs at the tissue level, causing profound edema (hydrops); congestive heart failure; and, in most cases, death in utero. These fatal complications do not occur in fetuses with Hb H disease because enough Hb F is made to sustain life.

α^+-Thalassemia trait is very common in black patients, having a genetic frequency of 20% to 30% in some populations. However, the *cis* α°-thalassemia deletion is rare in black patients. Thus, even though α^+-thalassemia trait and the *trans* deletion form of α°-thalassemia are very common, Hb H disease is rarely encountered, and hydrops fetalis has not yet been reported in black patients.[584,585]

Clinical Manifestations

Silent Carrier (α^+-Thalassemia Trait)

α^+-Thalassemia trait has no consistent hematologic manifestations. The RBCs are not microcytic, and Hb A_2 and Hb F are normal. During the newborn period, small amounts (≤3%) of Hb Bart (γ_4) can be seen by electrophoresis or other techniques. This condition is most often recognized when an apparently normal individual becomes the parent of a child with Hb H disease after mating with a person with α°-thalassemia trait. The mild excess of β-globin chains is probably removed in erythroblasts by proteolysis.[586] α^+-Thalassemia is particularly common in Melanesia, as well as in Southeast Asia and in African Americans, reaching a prevalence of more than 80% in north coastal Papua New Guinea. At the molecular level, α^+-thalassemia has been found to be associated with two common gene deletions resulting from different nonhomologous crossing-over events between the two linked α-globin genes: a 3.7-kb rightward deletion ($-\alpha^{3.7}$) resulting in a fused α2α1-globin gene and a 4.2-kb leftward deletion ($-\alpha^{4.2}$) resulting in loss of the 5′ (α2) gene.[581,582,587] The level of α-globin gene expression differs in the two conditions, as discussed in the following section.

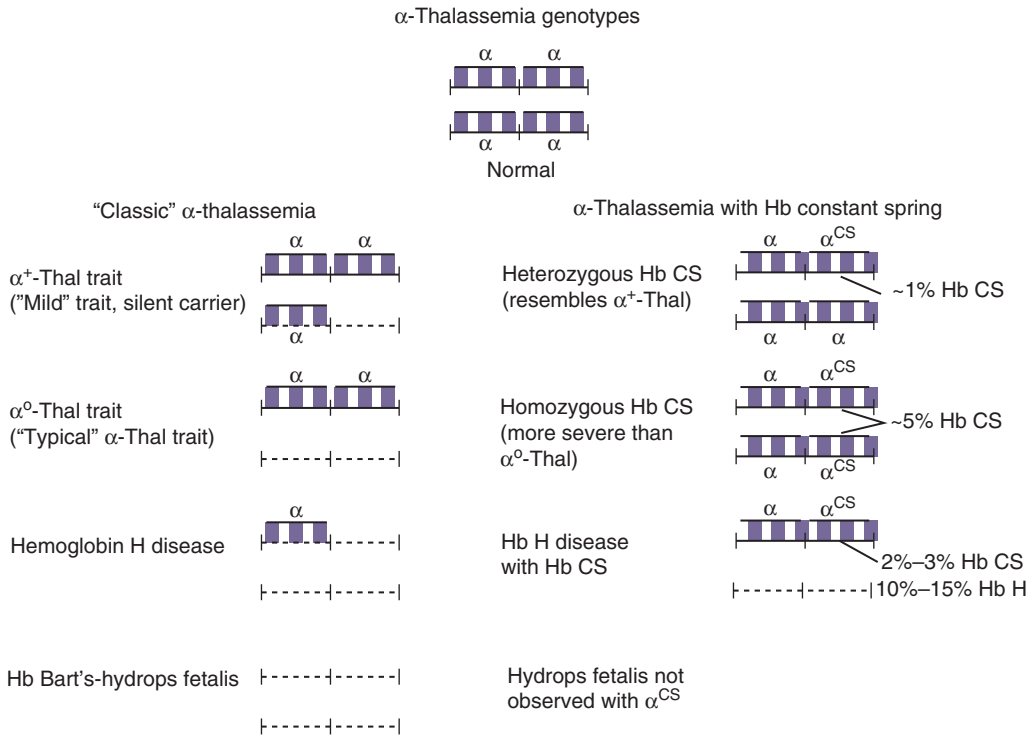

Figure 38-16 GENETIC ORIGINS OF THE "CLASSIC" α-THALASSEMIA SYNDROMES CAUSED BY GENE DELETIONS IN THE α-GLOBIN GENE CLUSTER. Hemoglobin (Hb) Constant Spring (CS) is an α-globin chain variant synthesized in such small amounts (1%-2% of normal) that it has the phenotypic impact of a severe nondeletion α-thalassemia allele; however, the α^{cs} allele is always linked to a functioning α-globin gene, so it has never been associated with hydrops fetalis.

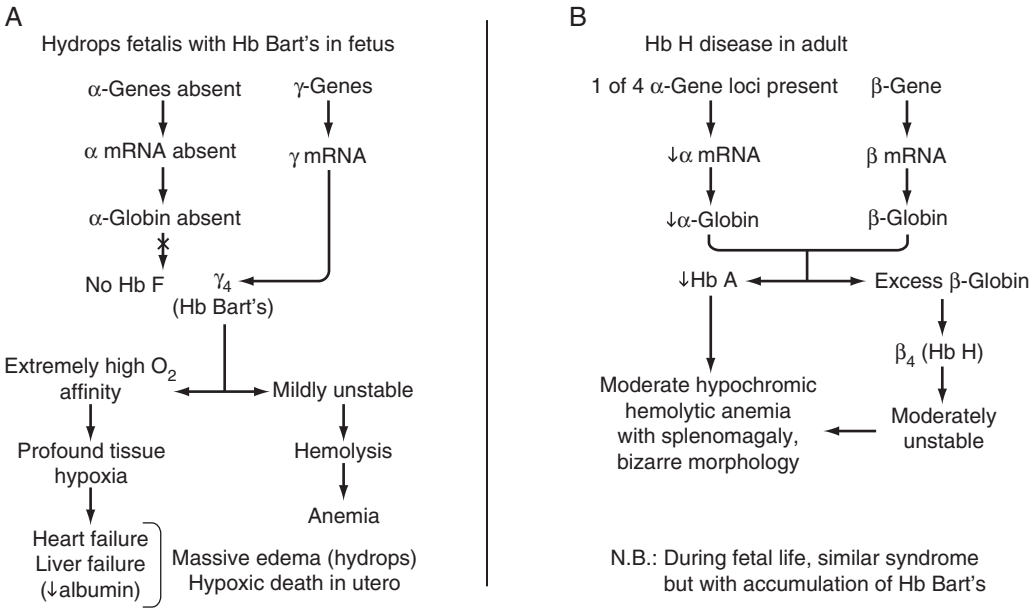

Figure 38-17 PATHOPHYSIOLOGY OF HEMOGLOBIN (HB) H DISEASE AND HYDROPS FETALIS WITH HB BART. *(Adapted from Benz EJ Jr: The hemoglobinopathies. In Kelly WN, DeVita VT, editors:* Textbook of internal medicine*, Philadelphia, 1988, JB Lippincott, p 1423.)*

α-Thalassemia Trait (α°-Thalassemia Trait)

Levels of Hb A_2 in the low to low normal range (1.5%-2.5%) and β/α synthetic ratios averaging 1.4:1 characterize α°-thalassemia trait. During the perinatal period, elevated amounts of Hb Bart are noted (3%-8%). Microcytosis is present in cord blood erythrocytes.

Studies of newborns from the archipelago of Vanuatu in the southwest Pacific and from Papua New Guinea indicate that homozygotes for the rightward $-\alpha^{3.7III}$ deletion (where only a fused α2α1-globin gene, mostly of the α2 type, remains) have lower Hb Bart levels (3.5% ± 0.8%) than those of infants homozygous for the leftward $-\alpha^{4.2}$ deletion (in whom only the α1-globin gene remains)

(6.0% ± 1.4%). These results suggest that the 5′ α2-globin gene has a higher output than the 3′ α1-globin gene, a conclusion supported by direct measurement of α2/α1 mRNA ratios.[588,589]

Hb H is not detected in hemolysates of peripheral RBCs, probably because of rapid proteolysis of Hb H or free β-globin chains. However, approximately 1% of erythroblasts and BM reticulocytes have inclusions. When an α-thalassemia gene occurs in persons who are also heterozygous for α-globin chain variant hemoglobins, such as Hb S, Hb C, or Hb E, the proportion of the abnormal hemoglobin is lower than that seen in simple heterozygotes.[590] The lower level of the abnormal hemoglobin is attributable to posttranslational control because of higher affinity of β^A chains for a limited pool of α-globin chains[591] coupled with proteolysis of the uncombined $\beta^{variant}$ chains.

Hb H Disease

Hb H disease is associated with a moderately severe but variable anemia resembling thalassemia intermedia, with osseous changes and splenomegaly.[592] However, the clinical phenotype may be considerably milder in some patients and severe enough to cause hydrops fetalis in others.[593,594] It occurs predominantly in Asians and occasionally in whites (Mediterraneans) but is rare in blacks. Exacerbations of anemia during febrile illnesses are common and are usually characterized by increasing fatigue and jaundice.

Because Hb H is unstable and precipitates within the circulating RBCs, hemolysis occurs. Hb H can be demonstrated by incubation of blood with supravital oxidizing stains such as 1% brilliant cresyl blue. Multiple small inclusions form in the RBCs (see Fig. 38-17). Electrophoresis of a freshly prepared hemolysate at alkaline or neutral pH demonstrates a fast-moving component amounting to 3% to 30% of the total hemoglobin. Concomitant iron deficiency may reduce the amount of Hb H in the patient's RBCs.[595] A syndrome of Hb H disease associated with mental retardation, other congenital anomalies, and large deletions on chromosome 16 has been noted in several white families.[596,597]

Hydrops Fetalis With Hb Bart
